ABSTRACT

CELLULAR AUTOMATA FOR CONTROL AND INTERACTIONS OF LARGE FORMATIONS OF ROBOTS

by

ROSS MEAD

Chairperson: Dr. Jerry B. Weinberg

In 2000, NSF and NASA met to discuss harvesting solar power in space to help meet future energy needs. One solution that received considerable attention was the use of robots to form a solar reflector. Imagine a space shuttle arriving in orbit, its bay doors opening, and a collection of thousands of individual robots, each with a piece of the reflector attached to them, float out into space. These robots then navigate themselves to form a large parabolic structure, which is then used to harvest solar energy. How can this *swarm*, or massive collection that moves with no group organization, coordinate to form an organized, global structure, or *formation*? Once organized, how can this formation be effectively controlled?

In previous work, I treated robots as cells in a 1-dimensional *cellular automaton*. Each robot “cell state” consists of its distance and orientation in 2-dimensional space in relation to neighboring robots. Using a *reactive control architecture*, these robots are able to establish and maintain formations defined by a single mathematical function. The viability of this approach was demonstrated in simulation with thousands of robots and on a physical platform with twelve custom robots. In order to attain formations necessary for applications such as the solar reflector, the algorithm must be generalized to 2- and 3-dimensional cellular automata. I now extend the algorithm to show how it can be generalized to 2-dimensional grid formations defined by multiple functions in order for form grid structures.

ACKNOWLEDGEMENTS

I would like to thank:

- Dr. Jerry B. Weinberg, for being a guide while still letting me explore off the beaten path. You have shown me—especially in your worst of times—that anything is possible—that I can be presented with limits and then push beyond them. I would not be where I am now without you. This work is dedicated to you.
- Cindy Scarsdale and the SIUE Undergraduate Research Academy, for your initial support of this project. The URA not only taught me the research process, but also how to present it and myself. It was during my time as a Scholar that I discovered that it is the questions—not necessarily the answers—that often provide the most interest. Cindy, you continue to inspire me with your motivation and support.
- Jeff Croxell, for your help as both a colleague and a friend—and, of course, soldering! You provided the hardware for my software madness. Without your wireless communication module, this work could not have been possible. Thank you for keeping me focused. Thank you for all of the laughs.
- Andrew Garrison, Justin Ratcliffe, and Andrew Nyambweke, for your tireless effort during the construction of this multi-robot platform. Andrew G. the original implementation provided necessary insight for robot identification. J.R., your “small hands” were critical in bringing all the pieces together to form a working robot; the robot faces worked better than I could have imagined, and the superglue provided a lot of laughs! Andrew N., thank you for being a one-man assembly line; good luck in all that you do.
- The students, faculty, and staff of the Department of Computer Science and the SIUE School of Engineering, for your continued support in this and other projects. It was your interest and feedback that motivated me to push myself to the next level.
- My band, Jinriksha, for your inspiration and creativity. “It’s time to see if I’m wanted here.”—Andy Sogor, Chadd Haselhorst, Tom Goodbrake, and Scott “Duck” Bryant, thank you for showing me that I was. Armadta Forever.
- My friends, and Sacred Grounds and Starbucks baristas and customers, for asking, “What the heck is that thing?” providing countless hours of discussion on robotics and its place in society. Your interest and encouragement in my work made me feel like I was doing something good with my life.
- My family, for always being there and for understanding when I could not be.

CHAPTER I

INTRODUCTION AND SIGNIFICANCE

Problem Statement

In April 2000, the National Science Foundation and the National Aeronautics and Space Administration held a joint workshop on autonomous construction and manufacturing for electrical power systems in space. In this workshop, participants explored harvesting solar power in space to help the world meet its future energy needs. This concept of Space Solar Power (SSP) involved placing a large solar collector panel or reflector panel in space and focusing a concentrated beam of energy on a panel on Earth that would be diverted to an energy plant for harvesting [4; Fig. 1].

Fig. 1: An Illustration of Space Solar Power. [7]

SSP has been recognized by *Popular Science* as one of the top 10 plans for clean, renewable power, stating that “space-based sun collectors could eventually meet all of our power needs” [7]. Recently, the Space Frontier Foundation sponsored a public online

discussion on the topic [<http://spacesolarpower.wordpress.com/>]. Many satellite concepts have been proposed, including the Suntower and the SolarDisc [16; Fig. 2]. However, none of these monolithic architectures have tackled “the biggest technical challenge: launching the device into orbit” [7]. For a large solar reflector that is potentially numerous kilometers in size, the difficulties and high-cost of transporting the necessary components for its construction, as well as the actual construction of the reflector itself, remain challenges that researchers would need to address.

Fig. 2: The Suntower (Left) and the SolarDisc (Right).

Purpose of the Project

One proposal that has received considerable attention is the use of robots for constructing a large solar panel. The original workshop report articulated one version of this solution in which the solar reflector is composed of a formation of many individual robotic units:

[The reflector is] actually created by having a swarm of coordinated independent semi-intelligent objects [(i.e., robots)] acting in concert. A solar reflector might be created in this way by having thousands of small free-flyers, each with a piece of mirror attached to themselves, fly into and then maintain a parabolic formation. One advantage of this strategy is that if the system is ever damaged, the swarm could reconfigure to eliminate the damaged elements but still maintain whatever level of uniformity might be required. [4]

This poses some interesting research questions. For example, once deployed, how does this large collection of robots communicate and coordinate their activities to form an organized parabolic structure resembling a reflector? How do the robots know when and where to move to maintain their position within the formation? And how can one operator or a small group of operators communicate with thousands of robots to effectively change the formation as needed? These questions have yet to be successfully addressed. Research in creating and maintaining organized formations of robots is a relatively new area of investigation, and implementation and testing has only been applied in simulation or on small groups of robots.

The need for algorithms for the control and interaction of robotic formations extends beyond that of SSP. For example, a large line formation could be implemented for the efficient planting and maintaining of uniform rows of crops. Coordinating large grid formations of robots has also been suggested for the “volumetric control” (surveying or monitoring) of some environment [25]. Additional applications include the autonomous navigation of various types of vehicles, ranging from automobiles to aircraft or watercraft. Recent applications for highway traffic control and safety are also being explored [9; Fig. 3].

Fig. 3: Robotic Highway Safety Markers. [9]

CHAPTER II

CONTEXT, BACKGROUND, AND LITERATURE REVIEW

The traditional artificial intelligence (AI) approach to robot control is known as *deliberative control*. In this “sense-plan-act” control schema, the robot senses its environment and, based on a symbolic representation of that environment (i.e., world model), creates a plan to take the appropriate action [17; Fig. 4]. While the deliberative control architecture may be advantageous in a static, known environment, it is subject to failure in the presence of unforeseen events with respect to the world model.

Fig. 4: The “Sense-Plan-Act” Paradigm. [17]

In contrast, a *reactive* system follows the “sense-act” paradigm, “tightly [coupling] perception to action without the use of intervening abstract representation or time history” [2, 17; Fig. 5]. Reactive control eliminates the need for a world model and traditional AI planning by, instead, relying on one or many simple behaviors [2, 5].

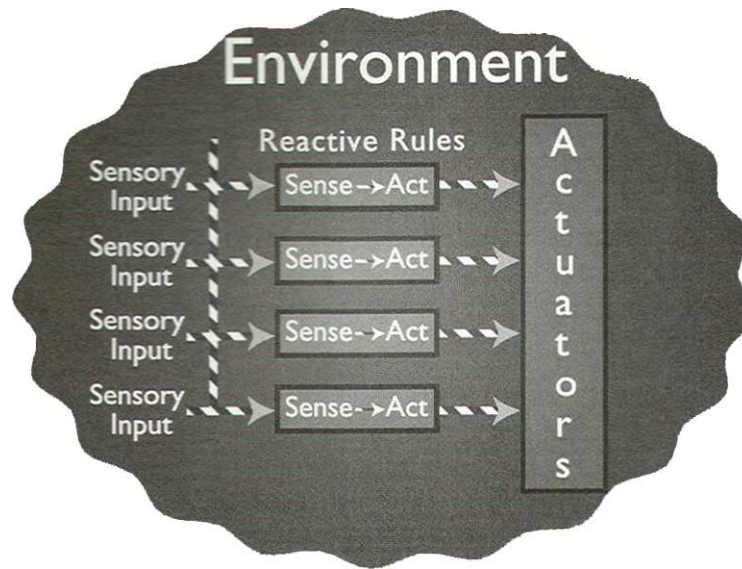

Fig. 5: The “Sense-Act” Paradigm. [17]

Seminal work by C. Reynolds [21] applies reactive control structures to show how individuals can exhibit emergent aggregate behavior similar to flocking birds. In this work, simulated birds alter their movement in three-dimensional space based on the direction, pitch, yaw, velocity, and distance of their neighbors. Flocking algorithms have been used for both physical [13] and simulated robots [1]. Distributed control methods based on gravitational physics [25] and gas particle interactions [6] have generated emergent structures. A digital hormone model, inspired by biological cell interaction, has also been proposed for robotic organization [24]. However, these apply more to swarms as opposed to formations, where a *swarm* is defined as a massive collection that moves with no group organization, much like a swarm of bees or a flock of birds [Fig. 6].

Fig. 6: Flock of Birds Demonstrating Swarm-Like Behavior. Note the Lack of Organization.

While a *formation* is similar, the distinction is made in that it maintains a global structure, much like a flock of geese or a marching band [Fig. 7 & 8]. Robot formations have been applied to applications such as automated traffic cones [9], while swarm behavior control has been applied to urban search-and-rescue robotics [27].

Fig. 7: Flock of Geese in Formation.

Fig. 8: Marching Band Formation, Demonstrating and Maintaining Well-Defined Organization.

Robots capable of attaching to one another have been proposed for formation applications. Tethered formation flight has been implemented on small robotic satellites in the SPHERES project [22; Fig. 9]. By keeping each tether taut, these robots are able to preserve their organization. Related work utilizes electromagnets and a reaction wheel to

control the position and orientation of a robot relative to another [14], but is currently limited in the number of units that can be controlled.

Fig. 9: Three SPHERES Satellites Maintain Formation by Keeping their Tethers Taut.

In [12], robots autonomously self-assemble into a single robotic configuration. These “swarm-bots” only interact with and connect to robots in their immediate vicinity and, thus, are able to self-organize without using a global coordination system [Fig. 10]. These types of strict connections make for a strong structure, but are rather restricted in their ability to change configurations. The challenges for applying a robot formation approach to SSP include generalizing the formation process, increasing the size of the robot formation, and formation management.

Fig. 10: Independent “Swarm-Bots” (Indicated by Blue Lights; Left) Connect with Others (Indicated by Red Lights; Right).

Previous work on maintaining formation has been applied on up to a dozen physical robots [20]; however, to better demonstrate group behavior on a larger scale, the number of mobile units must be increased. For a formation of robots numbering in the thousands, such as the 33,000 robots that Landis [15] projected would be needed for SSP, direct control through a remote teleoperation interface, in which an operator or a small group of operators must take control of each individual robot, is impractical. Rather, the robot formation will require some level of autonomous control. Computationally, the simplest robot control strategy is a form of reactive control where, in the case of formations, each robot responds to changes in its local neighborhood. It has the advantage of eliminating the need for each robot to maintain information about the global or overall structure of the entire formation.

This approach to the autonomous control of creating and maintaining multi-robot formations is similar to work done in coordinating formations of Earth-bound, mobile robots [3, 10, 11, 31]. Inspired by biological or organizational systems, such as the flight patterns of geese, Fredslund & Mataric [10, 11] assign a particular formation for robots to follow, such as a line, a V-shape, or a diamond [Fig. 11]. Each robot is given and transmits a position in the formation, an identification number, and the color of its corresponding “helmet”. Using a

combination of laser sensors, color tracking, and robot intercommunication, each robot is able to identify its “friend” (neighbor to reference). A robot leader is designated that transmits the specified formation. When the leader moves, neighboring robots adjust their orientation appropriately. In this way, the robot group is able to maintain a stable formation. However, this will only occur if the formation is moving; if the formation is not moving, robots are only able to determine their distance to their corresponding friend—true orientation is unknown. Because the robots are forced to move, an emergent restriction is imposed on the system: robots must follow (i.e., stay behind) their friend. Thus, formations are limited to those of non-frontal concavities with respect to the leading robot.

Fig. 11: An Overhead View of 4 Mobile Robots Traveling in a Diamond Formation. [10]

Utilizing reactive control techniques similar to flocking, Dudenhoeffer & Jones [8] demonstrate (in simulation) emergent robot organization in an environment that has been broken down into a 2-dimensional cellular automaton. A cellular automaton consists of a chain (1-dimensional) or lattice (2-or-3-dimensional) of computational cells, each cell being in one of a given set of states that evolve through discrete time steps [29]. The dynamic behavior of the automaton is determined by a set of rules that govern the change of state of an individual cell with respect to its neighbors.

Many practical implications must be considered when a given environment is represented topologically as a cellular automaton—referred to henceforth as a *world-space cellular automaton* [Fig. 12]. The next state of a robot within some cell depends solely on the occupancy state of cells within its neighborhood, which consists of the cell that the robot is currently in, as well as surrounding cells. This imposes strict limitations on the system. First, a robot must only occupy a single cell at any given time [Fig. 12a]. As robot movement is often inaccurate, this restriction can be difficult to satisfy without some form of external localization within the environment. Second, the robot must be bound to occupy only cells defined within the world-space. Thus, boundaries must be specified [Fig. 12b]. Moreover, rules for cells on the borders of a simulated automaton may allow for a type of wrapping to the opposing side to ensure proper neighborhood size [Fig. 12c]; however, in a physical implementation this is not feasible. Instead, specific rules must be in place for dealing with these boundary cells. Finally, many of the cells will be unoccupied, which, based on the specified rule set, has an effect on the next state of a robot. This increases the risk of collisions when two robots attempt to move to the same unoccupied grid cell [Fig. 12d]. Communication between robots would alleviate this, but would violate inherent restrictions in cellular automata if communication extends behind that of the neighborhood.

Fig. 12: Illustrates Various Limitations of 2-dimensional World-Space Cellular Automata: (a) Robot is between Grid Cells; (b) Boundary Surrounds the Automaton; (c) Automaton Wraps along Boundaries; (d) Two Robots Collide while Trying to Occupy the Same Grid Cell.

In keeping with a simple reactive control strategy, the approach of Mead *et al.* [19, 20] is to treat the robots in the formation as cells in a 1-dimensional *robot-space cellular automaton* [Fig. 13]. This distinguishes itself in that the actual robots that make up the global structure (i.e., not the structure itself) are represented by the cells. This approach overcomes many of the limitations inherent in a world-space automaton, eliminating the dependence on the environment and reducing the complexity of the automaton.

Fig. 13: Robots as Cells in a 1-Dimensional Robot-Space Cellular Automaton.

Each robot “cell state” consists of its desired and actual spatial orientation in 2-dimensional space in relation to neighboring robots. The robot’s behavior is governed by a set of rules for changing its state with respect to its neighbors. By designating a single robot as a “seed” or “initiator” cell of the formation, human intervention can change its orientation directly. This causes a type of chain reaction in the formation by each individual robot, which applies behavior rules based on the change in states of its neighbors. This is analogous to seeing a crowd in a baseball stadium “doing the wave”, where each individual’s reaction in the crowd is based solely on the people sitting nearby. The formation algorithm was initially implemented in simulation [19]. The simulator demonstrated the scalability and generality of the system, with over 3,000 agents conforming to a variety of different formations. In 2007, the feasibility of the approach was demonstrated on a physical platform [20; Fig. 14].

Fig. 14: Eleven Robots in a Parabolic Formation.

CHAPTER III

1-DIMENSIONAL ROBOT-SPACE CELLULAR AUTOMATA

In Mead *et al.* [19, 20], each robot is represented as a cell c_i in a 1-dimensional robot-space cellular automaton, where i refers to the index within the automaton; note that an index is not necessarily the robot's identification number or address that is used for communication—it is simply a reference. A cell consists of a neighborhood H , a state s , a formation definition F , and a step function S (each of these variable concepts will be described in detail throughout this chapter), written as:

$$c_i = \{H, s, F, S\} \quad (\text{Eq. 1})$$

Neighborhood

Each cell c_i is part of a neighborhood H_i , where:

$$H_i = \{c_{i-1}, c_i, c_{i+1}\} \quad (\text{Eq. 2})$$

Cells c_{i-1} and c_{i+1} refer to the left and right neighbors of c_i within the automaton, respectively. Likewise, a particular neighbor is denoted c_j , where j is the index of the cell representing a neighboring robot. It follows that, by combining the neighborhoods of all n cells, connectivity is enforced when defining the entire automaton C :

$$C = H_1 \cup H_2 \cup \dots \cup H_n \quad (\text{Eq. 3})$$

State

The state s_i of a cell c_i consists of the following variables: p , the relative position of the cell within the formation (referred to as *formation-relative position*); r_{des} , the set of all desired relationships with neighboring cells; r_{act} , the set of all actual relationships with neighboring cells; Θ , the rotational error of the robot within the formation; Γ , the translational error of the robot within the formation; t , the time step of the cell (each of these variable concepts will be described in detail throughout this chapter). Formally:

$$s_i = \{p, r_{des}, r_{act}, \Theta, \Gamma, t\} \quad (\text{Eq. 4})$$

In cellular automata, to determine the state s_i^t of c_i at time t , it must consider the state of all cells in H_i at the previous time step. A state transition step function—or *step function*— S (see State Transition for details on how this determines the state) can be written such that:

$$s_i^t = S(s_{i-1}^{t-1}, s_i^{t-1}, s_{i+1}^{t-1}) \quad (\text{Eq. 5})$$

Formation Definition

A desired formation F is defined by: $f(x)$, a geometric description (in this chapter, a single mathematical function); R , the desired distance to maintain between neighbors in the formation; Φ , the orientation of each robot relative to the formation on an x -/ y -coordinate system (referred to as *formation-relative orientation*); p_{seed} , a formation-relative position that serves as a starting point from which the formation and relationships will propagate.

$$F = \{f(x), R, \Phi, p_{seed}\} \quad (\text{Eq. 6})$$

This definition is sent to some robot, designating it as the *seed* cell c_{seed} of the automaton. Note that c_{seed} is not a leader, but rather an initiator of the coordination process.

State Transition

For purposes of establishing neighborhood relationships, a cell considers itself to be at some formation-relative position p_i (in the case of c_{seed} , p_{seed} is given in F):

$$p_i = [x_i \quad f(x_i)]^T \quad (\text{Eq. 7})$$

Relationships

Desired relationships. Relationships are determined by calculating a vector v from p_i to the intersection of $f(v_x)$ and a circle centered at p_i with radius R (given in F):

$$R^2 = (v_x - p_{i,x})^2 + (f(v_x) - p_{i,y})^2 \quad (\text{Eq. 8})$$

$$r_{i \rightarrow j, des} = [v_x \quad f(v_x)]^T \quad (\text{Eq. 9})$$

Solving for the *desired relationship vector* $r_{i \rightarrow j, des}$ to some neighbor c_j results in two intersections: one in the positive direction and one in the negative direction. These solutions define right and left neighbor relationships $r_{i \rightarrow i+1, des}$ and $r_{i \rightarrow i-1, des}$, respectively; these relationship vectors are then rotated by $-\Phi$, the negation of the given formation-relative orientation, so that robot heading is consistent within the formation definition [Fig. 15].

Fig. 15: c_i Calculates the Desired Relationships to its Neighbors.

The formation definition and relationship information are communicated locally within the H_i . Neighboring robots repeat the process, but consider themselves to be at different formation-relative positions as determined by the desired relationship from their neighbor. For a neighbor c_j :

$$p_j = p_i + r_{i \rightarrow j, des} \quad (\text{Eq. 10})$$

$$r_{j \rightarrow i, des} = -r_{i \rightarrow j, des} \quad (\text{Eq. 11})$$

Note that relationships $r_{j \rightarrow i, des}$ and $r_{i \rightarrow j, des}$ are equal in magnitude, but opposite in direction. This property of the algorithm is what guarantees convergence and stability between two robots attempting to establish and maintain relationships with one another. These calculated desired relationships generate a connected graph that yields the shape of the formation [Fig. 16].

Fig. 16: Calculated Relationships between Robots Generate a Parabolic Formation.

Actual relationships. Using only sensor readings, robots calculate an actual relationship $r_{i \rightarrow j, act}$ with a neighbor c_j (see [Robot Platform](#) for details on how this relationship is determined). The robot communicates locally (i.e., within the neighborhood) discrepancies in its desired and actual relationships to neighboring cells. Correcting for these discrepancies

produces a robot movement action A_i (discussed below) for each c_i , resulting in the overall organization of the desired global structure.

Motion control

By evaluating the state of the H_i , c_i is able to determine the translational error Γ_i and rotational error Θ_i (a difference from actual to desired) that will define its movement action A_i in the physical world:

$$A_i = [\Gamma_i \quad \Theta_i]^T \quad (\text{Eq. 12})$$

(For simplicity, A_i is assumed to be along a safe trajectory.)

To determine values for Γ_i and Θ_i , c_i must first seek a point of reference. Recall that the seed cell c_{seed} was given an initial formation-relative position p_{seed} , from which the formation and relationships propagate. As the distance from c_{seed} increases, the propagated error accumulates. It follows that the neighbor of c_i whose formation-relative position is closest to p_{seed} will have the least amount of propagated error within the system and, thus, will likely represent the most reliable robot to reference. This reference neighbor c_k is then the neighbor that yields the minimum distance $\|p_k'\|$ from p_{seed} to p_k :

$$k \mid p_k' = \min(\{\|p_{i-1} - p_{seed}\|, \|p_{i+1} - p_{seed}\|\}) \quad (\text{Eq. 13})$$

Rotational error. The rotational error Θ_i is a difference in robot orientation, which is propagated to each successive cell in the automaton. To determine Θ_i , c_i considers $r_{k \rightarrow i, act}$ with respect to itself. Let $\theta_{i \rightarrow k}$ represent the relative angle between the headings of c_i and c_k , and let θ_i and θ_k be the angles of the relationship vectors $r_{i \rightarrow k, act}$ and $r_{k \rightarrow i, act}$, respectively. Then:

$$\theta_{i \rightarrow k} = \theta_k - \theta_i + 180^\circ; [-180^\circ, 180^\circ] \quad (\text{Eq. 14})$$

$$\Theta_i = \Theta_k + \theta_{i \rightarrow k}; [-180^\circ, 180^\circ] \quad (\text{Eq. 15})$$

Note that when $\theta_{i \rightarrow k} = 0^\circ$, both i and k have the same global heading. The same holds true for every robot in the formation if $\Theta_i = 0^\circ$ for all i . This property of the algorithm to yield an emergent global heading is essential for any subsequent teleoperation from an operator. If a translational movement command is given, the common heading of the robots allows for a smooth transition in the same direction.

Translational error. The appropriate translational movement for each robot represented in the automaton is determined by an accumulation of error with both x- and y-components. This error is determined by the difference in desired and actual relationships of reference cell c_k . One major consideration is that many of the robots are, themselves, correcting for translational and rotational errors while they are being referenced by other robots. Changes in the orientation of c_k can cause rather entropic behavior in c_i , which depends on it for motion control. To alleviate this problem, $r_{k \rightarrow i, des}$ must be rotated, accounting for the propagated rotational error Θ_k within the automaton. Let $r_{k \rightarrow i, des}'$ denote $r_{k \rightarrow i, des}$ rotated by an angle $-\Theta_k$; γ_i can be expressed as the translational error of c_i with respect to c_k :

$$\gamma_i = \Gamma_k + r_{k \rightarrow i, des}' - r_{k \rightarrow i, act} \quad (\text{Eq. 16})$$

The Γ_k term represents the accumulation of error from c_k . Recall that $\theta_{i \rightarrow k}$ relates the headings of both of these robots, providing a conversion between the relative coordinate systems of c_i and c_k . Thus, rotating γ_i by $-\theta_{i \rightarrow k}$ yields the translational error Γ_i .

Formation Manipulation

To show the dynamic switching capabilities of the algorithm, a human operator can send a variety of commands to the seed cell, thus, propagating changes in the automaton and causing a chain reaction in neighboring cells, which then change states accordingly, resulting in a global transformation of the formation.

Formation translation

A translation command Ψ (with both x- and y- components) moves the robots relative to the current formation-relative orientation Φ_i . [Fig 17]. This is done by “tricking” the cells and taking advantage of the motion control system as defined above; simply add Ψ to the current translational error of the seed, and the error will be propagated:

$$\Gamma_{seed} = \Gamma_{seed} + \Psi \quad (\text{Eq. 17})$$

Fig. 17: Translation Command Sent to a Seed Cell Moves Formation Forward.

Formation rotation

A formation rotation command Ω causes a change in the orientation of the formation as a whole, thus, requiring each robot to move in such a way as to maintain the shape as it is rotated [Fig. 18]. Taking advantage, again, of the motion control system, the rotational error of the seed Θ_{seed} is simply rotated by Ω :

$$\theta_{seed} = \theta_{seed} + \Omega; [-180^\circ, 180^\circ] \quad (\text{Eq. 18})$$

Fig. 18: Formation Rotation Command Sent to a Seed Cell Rotates Entire Formation.

Cell rotation

A cell rotation command φ modifies the orientation of each cell relative to the formation; this contrasts to the formation rotation command in that the position and orientation of the formation itself relative to an external frame of reference remain unchanged [Fig. 19]. To do this, the seed cell prepares to perform a rotation in a similar way to that of a formation rotation command; it rotates θ_{seed} by φ . To prevent the entire formation from moving, it also rotates the formation-relative orientation Φ by this amount in the opposite direction and recalculates its desired relationships; this instigates a change in relationships through all cells in the automaton:

$$\theta_{seed} = \theta_{seed} + \varphi; [-180^\circ, 180^\circ] \quad (\text{Eq. 19})$$

$$\Phi = \Phi - \varphi; [-180^\circ, 180^\circ] \quad (\text{Eq. 20})$$

Fig. 19: Cell Rotation Command Sent to a Seed Cell Rotates Cells Individually; Formation Itself Appears Fixed in Place.

Formation scaling

A scaling command z stretches each of the desired relationships of c_i by the given scalar [Fig. 20]. For every neighbor c_j :

$$r_{i \rightarrow j, des} = z \times r_{i \rightarrow j, des} \quad (\text{Eq. 21})$$

Fig. 20: Scaling Command Sent to a Seed Cell Stretches Desired Relationships of Cells.

Formation resizing

A resizing command Z multiplies R (the distance that neighboring robots should stay apart) by this factor [Fig. 21]. This command is similar to the scaling command, but differs in that desired relationships must actually be recalculated using Equations (8 & 9) instead of being directly manipulated by some scalar:

$$R = Z \times R \quad (\text{Eq. 22})$$

Fig. 21: Resizing Command Sent to a Seed Cell Changes Cell Interval in the Formation.

Formation change

To change a formation, a seed cell is chosen and given the new geometric description, and the process described above is repeated [Fig. 22].

Fig. 22: Formation Change Command Sent to a Seed Cell Causes a Global Transformation; Pictured Here Transforming from $f(x) = a x^2$ (Parabola) to $f(x) = 0$ (Line).

Simulator

The control algorithm was initially implemented in a simulated environment [19; Appendix A—Simulator Code]. The simulator was written in C++ using OpenGL [www.opengl.org], and provides an easy means to visualize, manipulate, and test the algorithm; an operator may directly manipulate any cell, relocating or reorienting it to evaluate the stability of the system in the presence of error [Fig. 21].

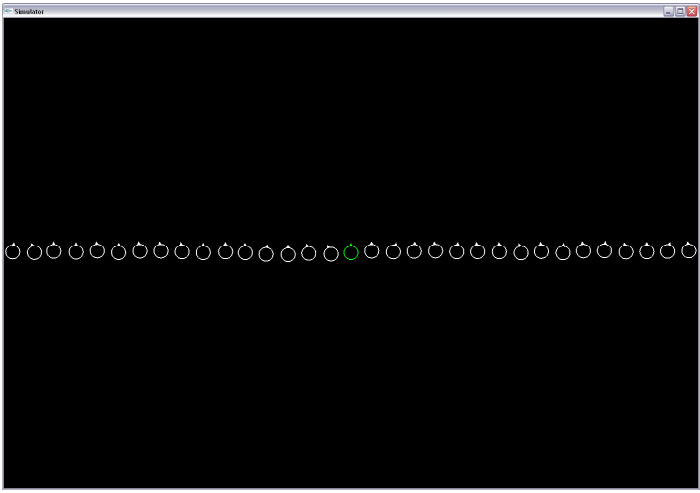

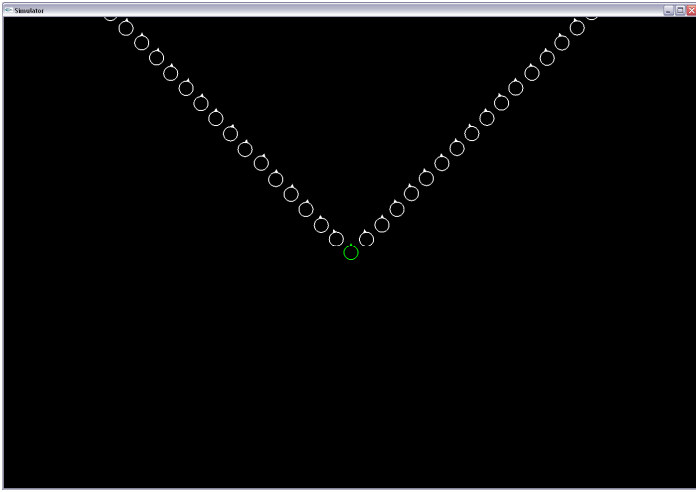

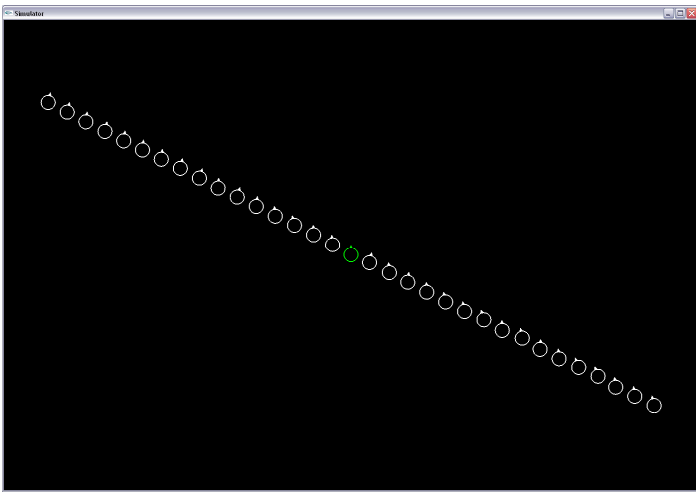

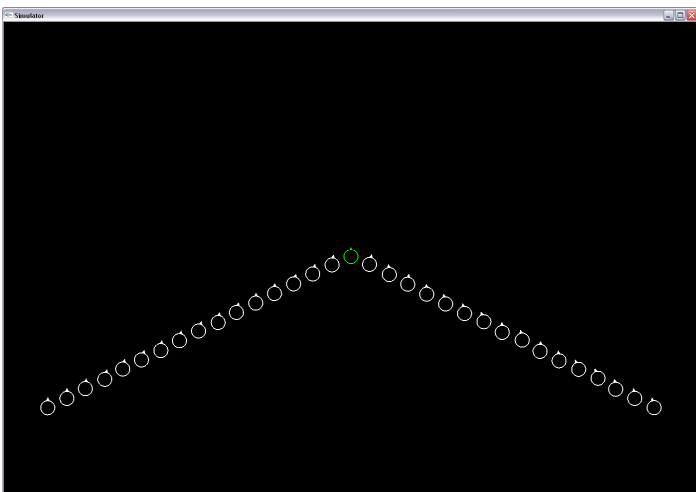

Fig. 23: Simulated Robots Change Formation from $f(x) = x^2$ (Parabola) to $f(x) = 0.05 \sin(10 x)$ (Sine Curve); Pictured at Four Time Steps.

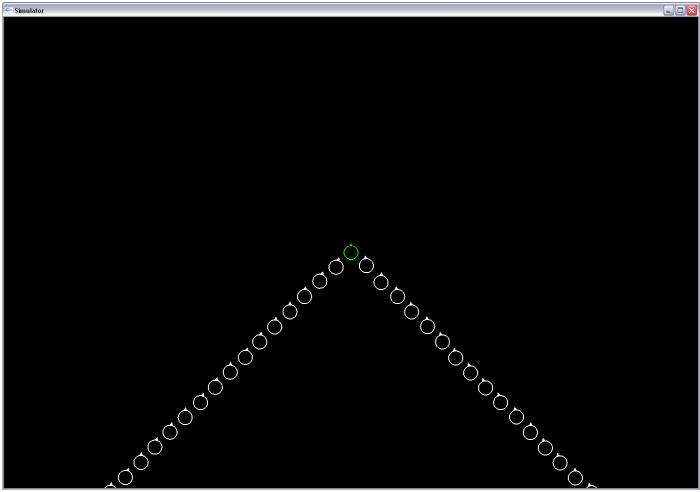

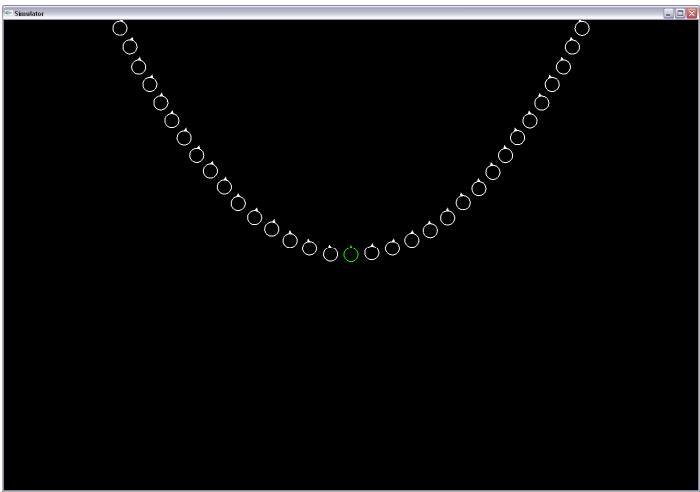

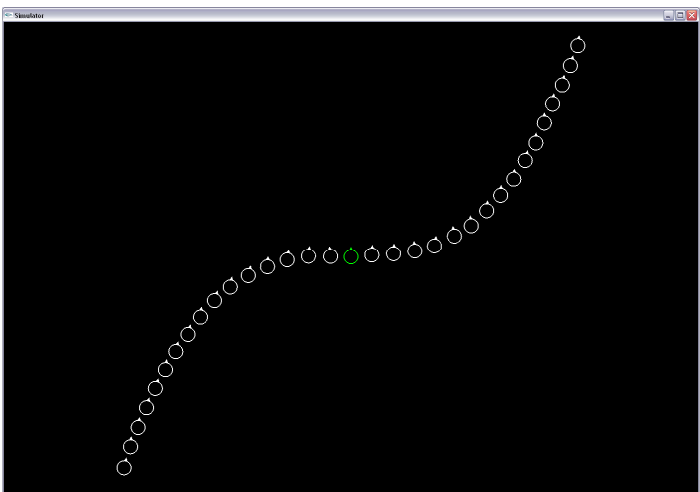

As before, each robot is represented as a cell c_i , where i is the corresponding index within the automaton; in the simulator, the automaton is stored as a 1-dimensional array of n cells, where n is given at runtime. Tens-to-thousands of cells have been tested against various formation definitions to demonstrate the scalability and generality of the algorithm [Table 1].

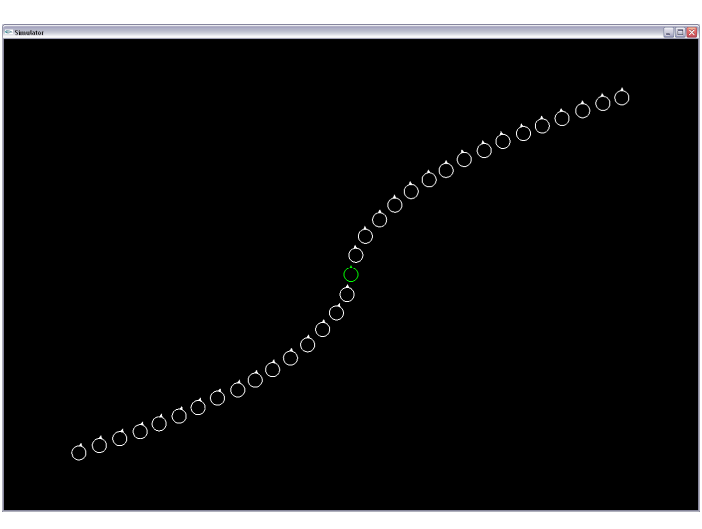

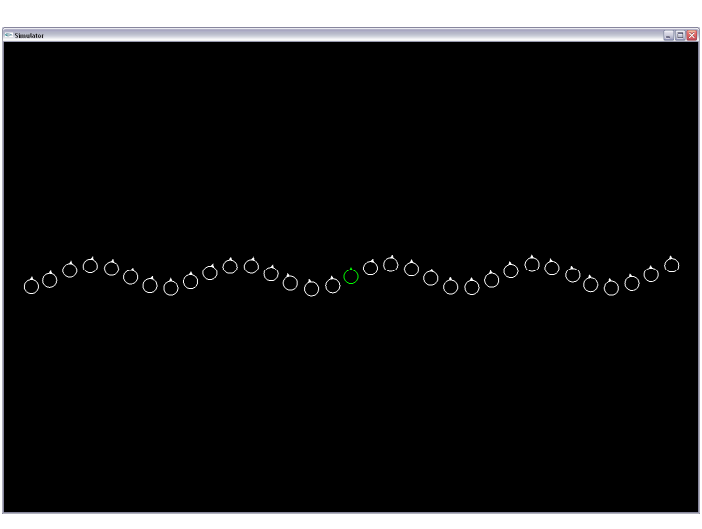

Table 1

SIMULATED FUNCTION-BASED FORMATIONS
(33 CELLS)

	$f(x) = 0$
	$f(x) = x$

	$f(x) = x $
	$f(x) = -\frac{1}{2} x$
	$f(x) = -\frac{1}{2} x $

	$f(x) = - x $
	$f(x) = x^2$
	$f(x) = x^3$

	$f(x) = \{-\sqrt{ x }, \text{ if } x < 0 \mid \text{ else, } \sqrt{x}\}$
	$f(x) = 0.05 \sin(10 x)$
<p>(Note that, for all formations shown here, $R = 10.5''$, $\Phi = 90.0^\circ$, $p_{seed} = [0.0 \quad 0.0]^T$.)</p>	

The simulator makes several simplifying assumptions. First, the array of cells is updated in discrete and synchronized time intervals; this alleviates any problems of inconsistency within the automaton. Second, each neighborhood has already been established; for a cell at index i , this neighborhood consists of the cells at the left and right indexes $i-1$ and $i+1$, respectively. Finally, each cell is assumed to have perfect, continuous, and unlimited sensing; thus, a cell is able to get its distance and orientation to any other cell at any point in time.

The next section discusses the physical implementation of this algorithm and how these assumptions were overcome to prove that the approach is viable in the real world.

Robot Platform

A platform was developed to test the algorithm in the physical world [20; Fig. 24]. Each robot is built upon a Scooterbot II base [www.budgetrobotics.com]. The Scooterbot is 7 inches in diameter and is crafted from expanded PVC, making it durable and light. Two modified servo motors are employed for differential steering.

Fig. 24: The Robot Platform.

Controller

The formation control algorithm is implemented in Interactive C (IC) [www.kipr.org/ic] and runs on an XBCv2 microcontroller [Fig. 25; www.botball.org]. The XBC utilizes back-EMF PID for accurate motor control. It also features a camera, capable of multi-color, multi-blob simultaneous tracking. Rotating the robot provides a 360° view of the environment and neighboring robots.

Fig. 25: XBC Microcontroller.

Neighbor localization

A neighboring robot represented by c_j is identified by either an orange or green color band; the color of each robot is assigned based on its ID: green for even; orange for odd. The alternating of color bands reduces the chances of overlapping color blobs and improves the accuracy of detecting a neighbor.

Relative distance. To locate c_j , a robot represented by c_i rotates until the band of the appropriate color is within its view; it then centers on that band. The heading of c_i is always considered to be directed at the x -axis (0°); relative to the robot, left yields positive angles and right yields negative angles. The distance $d_{i \rightarrow j}$ between c_i and c_j is determined by recognizing that the perceived vertical displacement Δy between the top and bottom of a color band is proportional to the perceived vertical displacement ΔY at a known physical distance D [Fig. 26]:

$$d_{i \rightarrow j} = D \times \Delta Y / \Delta y \quad (\text{Eq. 23})$$

Fig. 26: c_i Identifies and Determines its Distance to c_j .

Relative orientation. The relative orientation $\alpha_{i \rightarrow j}$ from c_i to c_j is simply the angular displacement from the initial location (i.e., prior to the search) of c_i . Thus, the *actual relationship vector* $r_{i \rightarrow j, act}$ is written in polar coordinates as:

$$r_{i \rightarrow j, act} = [d_{i \rightarrow j} \quad \alpha_{i \rightarrow j}]^T \quad (\text{Eq. 24})$$

Communication

Hardware. A radio communication module is used to share formation and state information within a robot's neighborhood. The XBee (ZigBee/IEEE 802.15.4 compliant) was chosen for its rich feature set [www.maxstream.net]. The module does not require a host/slave configuration, allowing for mesh networking and packet rerouting. The XBee also scales well for large applications, using 16-bit addressing to provide for over 65,000 nodes. The low-power model offers a range of 100 meters, which is equivalent to class-2 Bluetooth. The chip communicates using a TTL-level UART, while the XBC uses RS-232 levels. A PCB was designed by J.R. Croxell [20] to overcome level translation and to interface between the XBee and the XBC. All parts are surface mounted, with the exception of a 9-pin D-Sub male plug. The result is a board smaller than the XBee itself that directly plugs into the XBC's 9-pin serial port [Fig. 27].

Fig. 27: XBee Wireless Communication Module.

Software. MaxStream offers a wide range of functionality and extensive documentation for the XBee [29]; this eased the implementation and integration of a reliable packet communication system, supporting automatic retries and acknowledgements. The communication library developed allows values of different types to easily be “packed” (queued) into a buffer for sending and “unpacked” (dequeued) from a buffer when receiving (see [Communication.ic](#) in Appendix B—Interactive C Code for details). Packets can be addressed to a particular robot or broadcast. This allows each robot to communicate locally within its neighborhood, relaying and querying formation and state information.

Behaviors

The simulator made the simplifying assumption of robots updating and moving in synchronous discrete time steps. However, in the real world, one must consider that each robot will be updating and moving in asynchronous continuous time. This problem is alleviated by using a finite state representation to safely transition between a series of behaviors, while maintaining an internal counter (time step independent of system clock) of

events (state updates) that have occurred [Fig. 28]. This preserves the concept of discrete time in classic cellular automata.

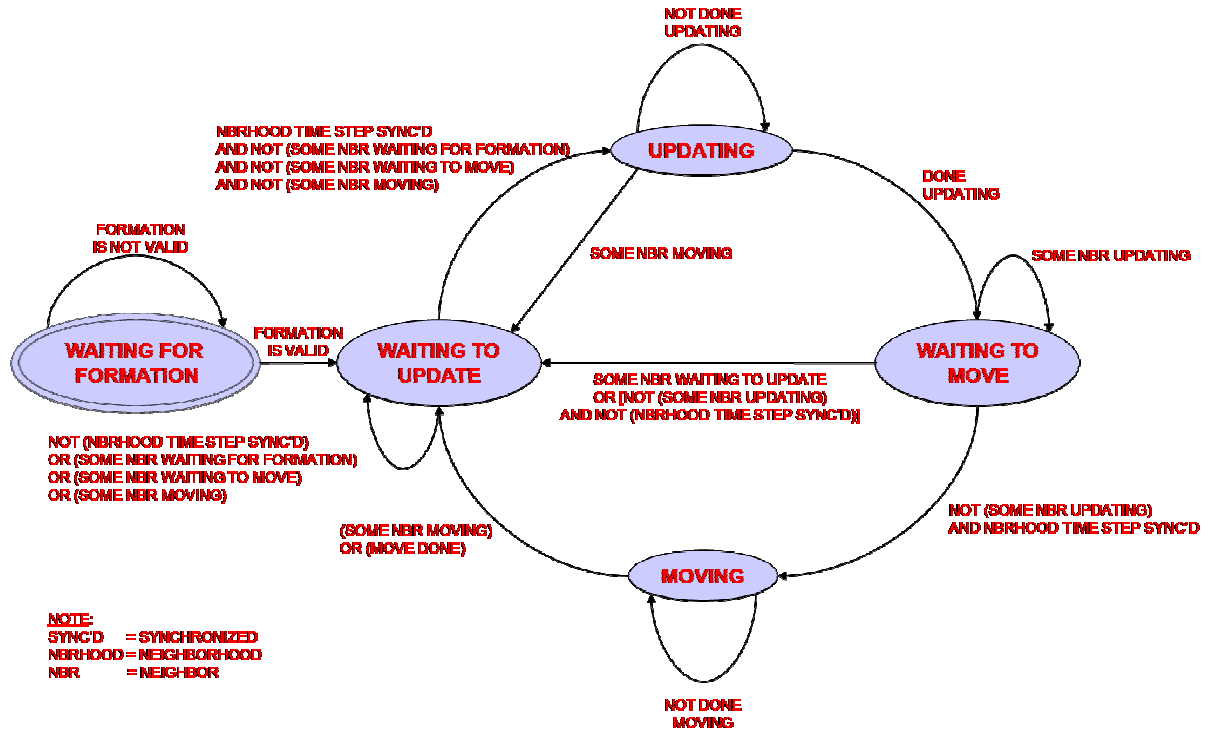

Fig. 28: Finite State Diagram of Robot Operation.

WAITING FOR FORMATION. This is the initial (entry-point) behavior of the robot. The robot will wait indefinitely until it receives a formation definition from either the operator (designating it as the seed cell in the automaton) or from a neighboring robot (queried at robot startup and/or relayed upon receiving a formation definition itself).

WAITING TO UPDATE. The robot must make certain that its neighbors are not moving or preparing to move before it updates its state, as a moving robot would make determining an instantaneous actual relationship impossible. This behavior also functions as a checkpoint for synchronizing the current time step t of a cell within its neighborhood; the

entire neighborhood is synchronized when all time steps are equal. To synchronize, the time step t_i of the cell c_i is set equal to the maximum of all neighborhood time steps:

$$t_i = \max(\{t_{i-1}, t_i, t_{i+1}\}) \quad (\text{Eq. 25})$$

This is particularly useful when introducing a new robot into the formation. At startup, its neighborhood is queried for a formation definition and, subsequently, the time step. With this information, a cell can seamlessly enter into the automaton.

UPDATING. During the update process, the robot determines its actual relationship to each neighbor within its neighborhood (see *Neighbor localization* above for how this relationship is determined). The robot then calculates its translational and rotational error, increments its time step t_i , and finally communicates its new state s_i^t locally within its neighborhood.

WAITING TO MOVE. This behavior is similar to the WAITING TO UPDATE behavior; the robot must wait until all neighbors are done updating before moving. Once all neighbors are done updating, their time steps should all be synchronized. If an inconsistency occurs, the robot reports an error and returns to the WAITING TO UPDATE state for synchronization.

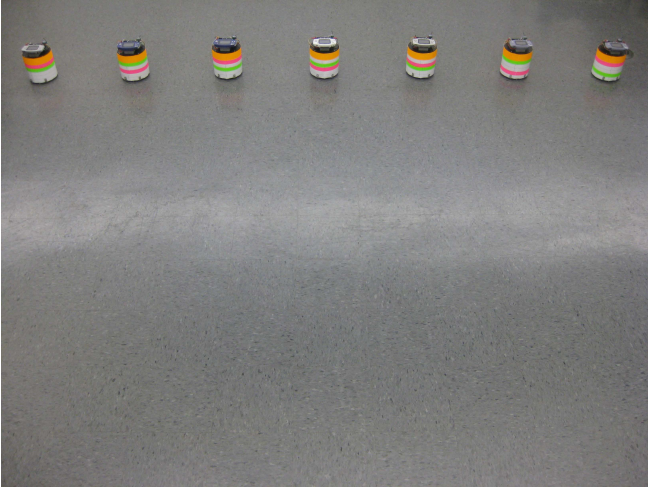

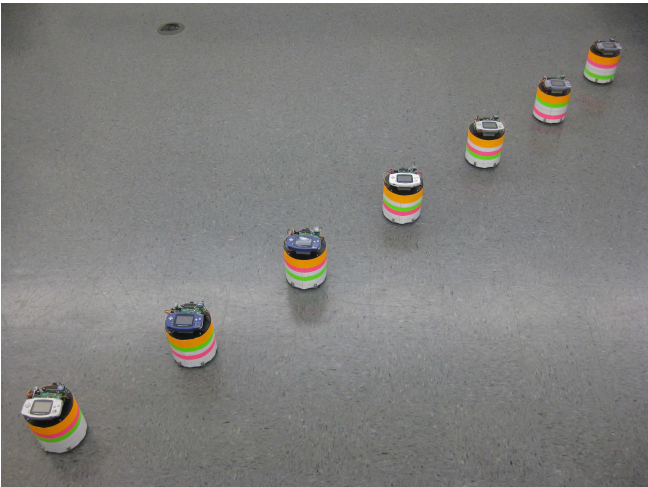

MOVING. While executing this behavior, the robot actually attempts to correct for its calculated error, translating and rotating based on its movement action A_i . Upon completion, the translational and rotational error are approximately 0, and the state is updated to reflect this; the time step t_i is incremented for this state change, and the state s_i^t is communicated to the neighbors of the cell.

Implementation Results

The algorithm was implemented on a variety of different formation using twelve of these robots (shown below in different numbers with different identification bands, as these pictures were taken during the process of this thesis; see [Neighbor Identification](#) in the next chapter for how these robots are identified).

Table 2

IMPLEMENTED FUNCTION-BASED FORMATIONS (7 ROBOTS)

	$f(x) = 0$
	$f(x) = x$

$$f(x) = |x|$$

$$f(x) = -\frac{1}{2}x$$

$$f(x) = -\frac{1}{2}|x|$$

$$f(x) = -|x|$$

$$f(x) = \frac{1}{64} x^2 \text{ (16.0" focus)}$$

$$f(x) = (0.1 x)^3$$

$$f(x) = \{-5 \sqrt{|x|}, \text{ if } x < 0 \mid \text{ else, } 5 \sqrt{x}\}$$

$$f(x) = 8 \sin(3 x)$$

(Note that, for all formations shown here, $R = 24.0''$, $\Phi = 90.0^\circ$, $p_{seed} = [0.0 \quad 0.0]^T$.)

Also, the perspective of the camera was changed to keep seven robots in the image.)

CHAPTER IV

2-DIMENSIONAL ROBOT-SPACE CELLULAR AUTOMATA

Goals and Objectives

Extending the formation control algorithm to be applied to SSP, the global structure of the solar reflector array could be viewed as a 2-dimensional lattice of robots. In [10, 11, 19, 20, 28], the formations were setup so each robot only needed to identify two neighbors. In the reflector formation, the definition of a neighborhood becomes more complex. There are various neighborhoods defined for cellular automata, such as the von Neumann Neighborhood (four surrounding cells), Moore Neighborhood (eight surrounding cells), and the Extended Moore Neighborhood (includes cells adjoining the immediate eight surrounding cells) [23]. Landis [15] provides insight into potential physical configurations of robots for SSP and this is considered in determining the appropriate number of neighbors for a given formation [Fig. 29]. The proper neighborhood definition for the automaton is crucial because it will directly affect how each robot cell reacts, how information gets propagated through the formation, and influences the overall performance of the formation by increasing or decreasing the communication and sensing overhead.

Fig. 29: Potential Arrangement of Robotic Units to Form a Tight Lattice Structure. [15]

Extending the Formation Definition

Mead *et al.* [19] identified the potential for different categorizations of formations (see *Formation classification* in the next chapter for a preliminary analysis), including those that are defined by multiple functions. To do so, the initial formation definition F must be extended to include more than one function. Let f' be a set of M mathematical functions used to define the shape of the formation, such that F in Equation (6) can be extended:

$$f' = \{f_1(x), f_2(x), \dots, f_M(x)\} \quad (\text{Eq. 26})$$

$$F = \{f', R, \Phi, p_{seed}\} \quad (\text{Eq. 27})$$

Each function is considered individually for purposes of calculating desired relationships and, thus, generates its own 1-dimensional neighborhood as before; this results in M neighborhoods. To extend Equation (2), consider a neighborhood ${}^m h_i$ for a single function $f_m(x)$, where $1 \leq m \leq M$:

$${}^m h_i = {}^m \{c_{i-1}, c_i, c_{i+1}\} \quad (\text{Eq. 28})$$

The combined neighborhood can then be represented as the union of all M neighborhoods:

$$H_i = {}^1 h_i \cup {}^2 h_i \cup \dots \cup {}^M h_i \quad (\text{Eq. 29})$$

Note that c_i is unique within the automaton as a whole and is a common intersection of each neighborhood for each function; to illustrate this, H_i can be expanded:

$$H_i = \{{}^M c_{i-1}, \dots, {}^2 c_{i-1}, {}^1 c_{i-1}, c_i, {}^1 c_{i+1}, {}^2 c_{i+1}, \dots, {}^M c_{i+1}\} \quad (\text{Eq. 30})$$

Similar to its previous definition, any particular neighbor can be written as ${}^m c_j$, where m refers to the function upon which j is an index to a neighboring cell. It follows that the step function S must also consider the new neighborhood for purposes of calculating the state s_i^t :

$$s_i^t = ({}^M s_{i-1}^{t-1}, \dots, {}^2 s_{i-1}^{t-1}, {}^1 s_{i-1}^{t-1}, s_i^{t-1}, {}^1 s_{i+1}^{t-1}, {}^2 s_{i+1}^{t-1}, \dots, {}^M s_{i+1}^{t-1}) \quad (\text{Eq. 31})$$

This distinction is especially important for determining the aforementioned reference neighbor c_k ; extending Equation (13) to consider all neighbors within a neighborhood defined by multiple functions, the identity of c_k can still be determined. The reference neighbor c_k can be defined, similar to before, as the neighbor that with the minimum distance $\|p_k'\|$ from p_{seed} to ${}^m p_k$, where m refers to the function upon which k is the index to the cell to be referenced:

$$k | p_k' = \min(\{\|{}^M p_{i-1} - p_{seed}\|, \dots, \|{}^2 p_{i-1} - p_{seed}\|, \|{}^1 p_{i-1} - p_{seed}\|, \|{}^1 p_{i+1} - p_{seed}\|, \|{}^2 p_{i+1} - p_{seed}\|, \dots, \|{}^M p_{i+1} - p_{seed}\|\}) \quad (\text{Eq. 32})$$

Formations Defined by Multiple Functions

As an example and for purposes of SSP [15], consider a hexagonal lattice structure by defining a formation F by three functions: $f_1(x) = 0$, $f_2(x) = x\sqrt{3}$, and $f_3(x) = -x\sqrt{3}$. For c_{seed} , solving for Equations (8 & 9) for each of these functions yields a total of six desired relationships [Fig. 30].

Fig. 30: A Formation Defined by Three Functions Yields Six Relationships.

As before, the definition and relationships are propagated to neighboring cells, which repeat the process. However, using the standard implementation of the algorithm, the resulting formation would be a sort of “six-armed structure” [Fig. 31].

Fig. 31: A Three-Function Formation Definition Generates a Sort of “Six-Armed Structure”.

The formation of this structure is the product of the p_i term in Equation (8), which considers the cell c_i to be at position p_i on some function and, in turn, affects the calculation of desired relationships in Equation (9). While this may be desirable for some applications, it deviates from the goal of a lattice. By removing the p_i term from Equation (8), all cells will be considered at the origin when calculating their desired relationships on all M functions:

$$R^2 = v_x^2 + f_m(v_x)^2 \quad (\text{Eq. 33})$$

Note that the p_i term does not leave the algorithm completely—it is still propagated within the automaton for purposes of determining the reference neighbor in Equation (31). This seemingly minor change produces significant results: cells begin to develop common

neighbors as neighborhoods intersect one another; an emergent hexagonal lattice structure results [Fig. 32].

Fig. 32: A Three-Function Formation Definition Produces a Hexagonal Lattice Structure.

Now, consider using the functions $f_1(x) = x$ and $f_2(x) = -x$ to define F in order to generate a square lattice [Fig. 33].

Fig. 33: A Formation Defined by Two Functions Yields Four Relationships.

Similarly to that of the hexagonal lattice attempt, if the standard implementation is used, a “four-armed structure” results that was not intended (but nonetheless interesting) [Fig. 34].

Fig. 34: A Two-Function Formation Definition Generates a Sort of “Four-Armed Structure”.

However, as before, by utilizing Equation (33) for purposes of determining desired relationships, the desired lattice forms from this multi-function definition [Fig. 35].

Fig. 35: A Two-Function Formation Definition Produces a Hexagonal Lattice Structure.

Neighbor Identification

For a robot to determine its state, it must be able to identify its neighbors. This is easier said than done, as each unit looks identical. The problem is analogous to being in a room of people that look and dress exactly alike; if one person speaks (i.e., sends a message) without further sensory input, such as auditory localization, it is impossible to determine who was speaking. A colored bar-coding system is utilized to alleviate this problem; each robot features a unique “face”—a three-color column, where the vertical locations of the green and magenta bands (in relation to the orange band) correspond to its identification number [Fig. 36].

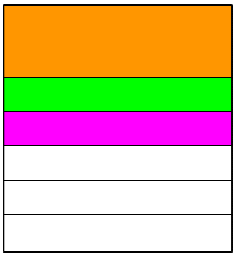

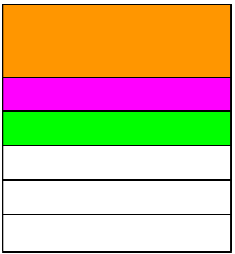

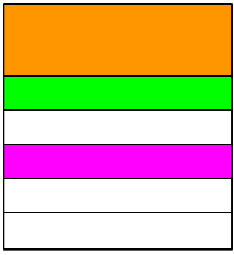

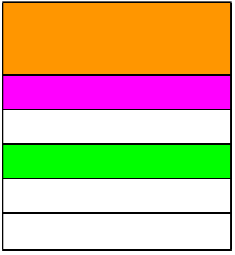

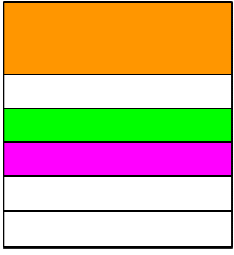

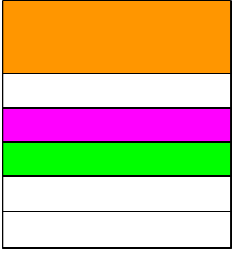

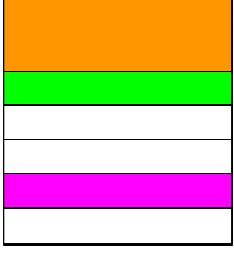

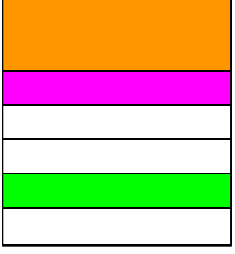

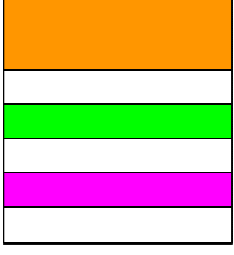

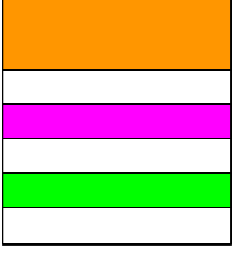

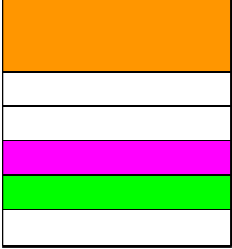

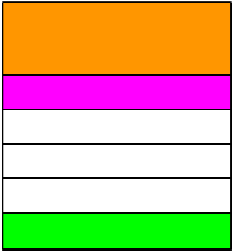

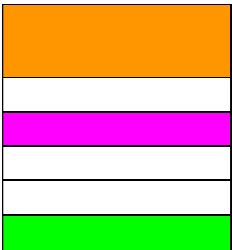

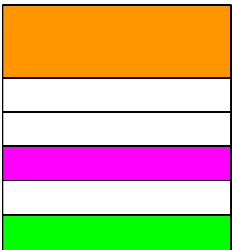

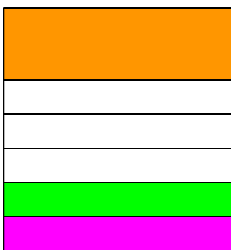

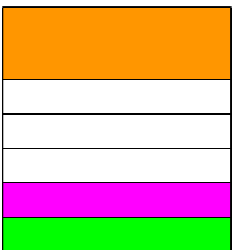

Fig. 36: c_i Identifies the “Face” of c_j and Determines its Relative Distance.

Relative distances are calculated as in Equation (22) using only the orange color bar at the top. However, for an orange band in a camera frame to even be considered a neighboring robot, it now must also possess a green band and a magenta band at some nearby position beneath it; based on the proportions of the size of these bands in the physical world, it is simple to tell whether or not a perceived combination of bands in a frame is valid. The identification number of the robot is determined based on the following table (note that, when the green band is above the magenta band, this number is even and vice versa):

Table 3

ROBOT FACES

	0		1
	2		3
	4		5
	6		7
	8		9

	10		11
	12		13
	14		15
	16		17
	18		19

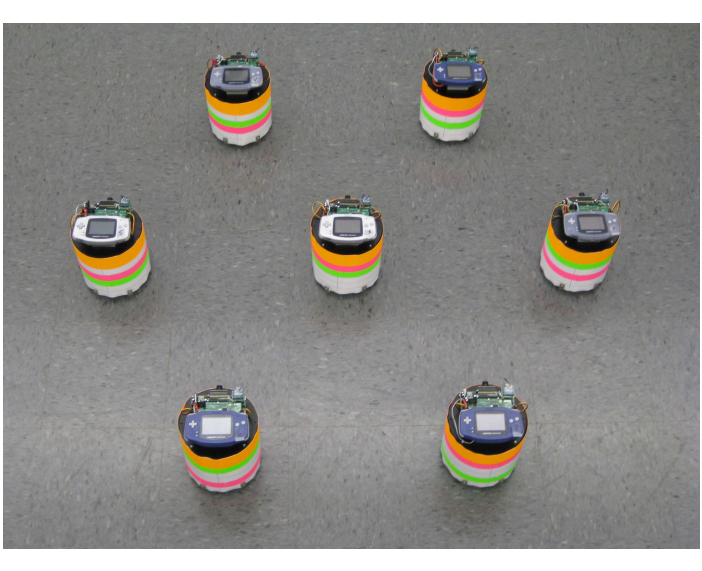

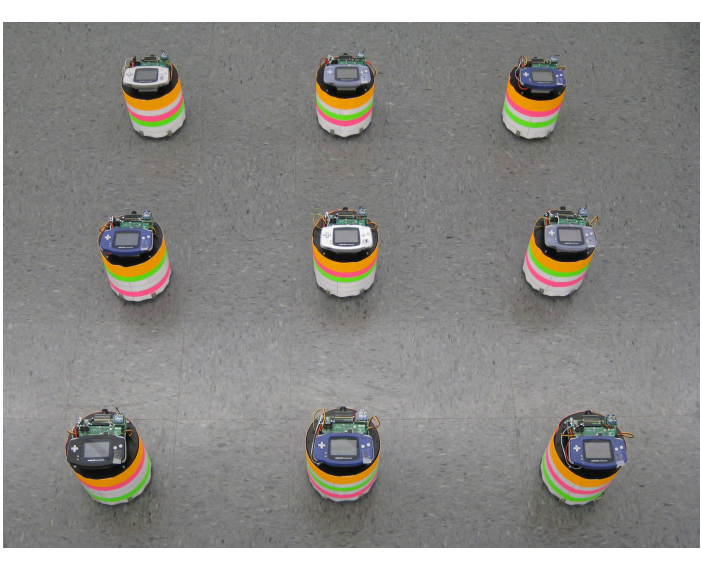

While a greater number of robots could have been identified using all permutations of color combinations, requiring that all three color bands be present and that one be in a fixed position simplifies vision processing, while still providing enough unique identifiers for the number of robots implemented.

Implementation Results

This extension of the algorithm was implemented and tested on 19 “face-lifted” robots (shown below in different numbers) [Table 4]. Integration with the previous implementation was seamless, as relationships are calculated for any number of functions. A flag is set to specify whether Equation (8) or Equation (33) is to be used.

Table 4

IMPLEMENTED GRID FORMATIONS

	$f_1(x) = 0$ $f_2(x) = x \sqrt{3}$ $f_3(x) = -x \sqrt{3}$ $R = 24.0''$ $\Phi = 90.0^\circ$ $p_{seed} = [0.0 \quad 0.0]^T$
	$f_1(x) = x$ $f_2(x) = -x$ $R = 24.0''$ $\Phi = 45.0^\circ$ $p_{seed} = [0.0 \quad 0.0]^T$

CHAPTER V

CONCLUSIONS

Summary and Discussion

Algorithm

A general purpose distributed robot formations algorithm has been presented. Robots are represented as cells in a “robot-space cellular automaton”. Connectivity of the automaton is guaranteed as it is expressed as the union of all cell neighborhoods. A human operator sends a formation definition to some cell, designating it as the seed of the automaton. It is emphasized that this cell is not a leader, but rather an initiator of the coordination process—thus, this algorithm distinguishes itself as being leaderless. Each robot cell state consists of its distance and orientation in 2-dimensional space in relation to neighboring robots. Using only local information, these robots are able to establish and maintain a variety of formations.

As described in Chapter III, the initial conception of the algorithm considered formations defined by a single mathematical function [19]. Motivated by SSP, the algorithm was generalized such that a formation could be defined by any number of mathematical functions—the goal: to produce grids. Using Equation (8) to solve for desired relationships with neighboring robots, it was discovered that oddly—but interestingly—shaped “armed structures” would emerge; this result was intuitive, as a cell’s function-relative position is used in this calculation. In order to achieve the desired lattice structures, an alternative equation—Equation (33)—was developed that omitted this cell property. The result: hexagonal and square lattices (see Implementation Results in Chapter IV for details).

Formation classification. Previous work [19] and observations in the previous chapter (see Formations Defined by Multiple Functions for details) lead to a preliminary classification of formations that can be represented as robot-space cellular automata in this algorithm; further study is necessary to develop an exhaustive list, and is left as future work.

- I. *Non-formation (swarm)*—A distinction has already been made between a swarm and a formation (see Fig. 6 for an example)—the former does not assume any particular organization, while the latter requires a definite structure. Nonetheless, swarms have a place in the algorithm, likely represented by 2-dimensional cellular automata. From Equation (26), consider a situation where $M = 0$ and, thus, f' is an empty set. Given a formation defined in this way, it is clear that desired relationships are unable to be calculated using either of Equations (8) or (33); however, variables R and Φ in the formation definition provide enough information to demonstrate some interesting behavior. Robots still must maintain a range R to one another. This type of definition is similar to the approaches taken by [6, 25] and has the possibility of generating emergent lattice structures; however, as previously stated, this situation is less controlled and would not be a reliable method for grid organization. Robots can also use Φ to generate a common heading. McLurkin [18] utilizes the ability of swarm robots to orient to the same heading in order to follow a beacon. Note that, in any case, a neighborhood must be considered. For a generic swarm and a cell c_i , its neighborhood H_i could simply be all cells in the automaton (i.e., $H_i = C_i$). Other applications may provide a specific neighborhood definition or even allow the neighborhood to be dynamically determined based on robots in proximity.

- II. Explicit formation*—As in Class I, a formation is defined with $M = 0$ and f' as an empty set. However, this classification differs in that strict (explicit) relationships (and potentially neighborhoods) are provided (much like how a marching band is formed, as in Fig. 8). The dimensionality of the automaton would be based upon the configuration of neighborhoods and the relationships within them. This categorization provides opportunity for nearly any type of structure or shape imaginable, in that the formation is not restricted to being defined by one or many mathematical functions. While a wide variety of different formations could be generated by this approach, it is likely unappealing as there is a considerable amount of overhead associated with individually specifying neighborhood relationships for each cell.
- III. Straight line formation*—It has been observed that formations defined by single functions usually require the use of Equation (8) when determining desired relationships—this is intuitive. Recall that Equation (11) holds that, for a formation to be stable, the calculated relationships between neighbors must be equal in magnitude, but opposite in direction; if Equation (33) were used on a single-function formation, the latter of these two claims would not be true—indeed, the relationships would be equal in magnitude, however, they would *not* be opposite in direction. The only exception to this noted thus far is in the case of $f(x) = a x$ (i.e., any straight line; see Fig. 22); this is due to the fact that the set left and right relationships will be the same for any formation-relative position used in the calculation of Equations (8 & 9). Thus, for formations in this category, either Equation (8) or Equation (33) can be used for purposes of calculating desired relationships. The nature of the line also suggests that this category will be represented by a 1-dimensional cellular automaton.

- IV. *Function-based formation*—This classification is based on the initial definition of the formation control algorithm in the previous chapter and, for this reason, is considered the simplest (represented as a 1-dimensional cellular automaton), most general (conforming to a variety of different functions), and most clearly stable (see Eq. 11 for a description of why it is stable) type of formation identified. For purposes of calculating desired relationships, Equation (8) is used.
- V. *Branching formation*—Formations in this category describe those previously referred to as “armed structures” (see Figs. 31 & 34)—the use of the “branching” descriptor comes from the notion that each “arm” is like a “limb” (or “branch”) of the formation. Multiple functions are used to define a formation (i.e., $M > 1$), and Equation (8) is used to calculate desired relationships. This category has the interesting result of forming neighborhoods with nonstandard sizes, as a cell with a formation-relative position on a “branch” would likely have a smaller neighborhood than that of those cells closer to the seed. For this reason, these neighborhoods must be formed dynamically to alleviate the overhead of operator-definition (see *Dynamic Neighborhoods* in the next chapter for details). Combining neighborhoods would generate a 2-dimensional cellular automaton, albeit somewhat irregular.
- VI. *Lattice formation*—In Chapter IV, it was shown that these types of formations form tight, interlaced grids through the use of Equation (33) for desired relationship determination. Unlike those in Class V, these types of formations have a standard neighborhood size in a 2-dimensional automaton. Potential for collisions is high, as robots will be working in proximity of one another; however, the grid still remains stable as Equation (11) still holds.

Erroneous relationships. In extreme cases of any class of formation, it is theoretically possible to calculate more than two desired relationships for a given function [Fig. 37].

Fig. 37: A Formation Definition Yields Erroneous Relationships.

Fortunately, this problem is easy to alleviate. Recall that both Equations (8 & 33) solve the roots for the vector v , which are then used in Equation (9) to determine $r_{i \rightarrow j, des}$ for all neighbors. In the case that v yields more than two solutions, one simply considers that, to maintain a sense of continuity on a function, the two values of v_x nearest to the x -component of the formation-relative position $p_{i,x}$ of cell c_i produce the proper neighbor relation. In other words, the two relationships that are valid are those that minimize the function:

$$e(v) = |v_x - p_{i,x}| \quad (\text{Eq. 34})$$

Robot platform

Hardware. A total of 19 robots were developed for the purpose of this project. These robots are homogeneous in terms of hardware—atop a two-wheeled ScooterBot II base sits an XBCv2 microcontroller with a color camera; an XBee wireless communication module with a custom interface to the XBC allows for inter-robot communication. A colored bar-coding system was used for neighbor identification, with each robot featuring a unique “face”.

The wheeled platform performed better than expected, demonstrating very accurate motion control (via back-EMF) with minimal slippage on the tile surface used for testing. robot symmetry likely balanced the effects of environmental dynamics, aiding in such positive locomotive results. The size of the robot is ideal for multi-robot systems, as it is large enough to facilitate the aforementioned hardware (with room for sensor expansion, if desired), while being small enough such that a large collection of robots can actually be tested in an average-sized room. The robots are also very sturdy, surviving a few tumbles in the lab and during travel. For these reasons, the ScooterBot base is recommended as an inexpensive and easy-to-use platform for single- and multi-robot systems.

The requirements of the formation control algorithm (in terms of motion control, data communication, and vision processing) promised to push the XBC to its limits—fortunately, the microcontroller was up to the task. Computation power and program execution time proved to be more than adequate for the purposes of this work. The color camera performed well; tracking blobs of preprogrammed color models (orange, green, and magenta) was consistent across all robots; auto white-balancing allowed for adaptation to different lighting conditions. Note that, since the XBCv2 has a serial interface, downloading programs can be rather time-consuming. An alternative would be to use the XBCv3, which is USB-based,

thus, decreasing download time; however, in order to utilize wireless communication, a new interface board would have to be created.

The XBee module and PCB provided transparent serial communication between robots, which used packet addressing to propagate information within their respective neighborhoods. Acknowledgements and automatic retries implemented on the chip itself reduced the amount of packet loss. In cases where a large amount of data is being relayed, transmission time can be high, but not unreasonable. The most notable problems with serial communication resulted from its integration with software (discussed below). Given the algorithm's high dependence on communication, the module proved to be very reliable.

Robot “faces” were the hallmark of the robot platform, as robots were able to consistently identify and localize with their neighbors—results were better than expected. Initial estimates showed that a robot would only be able to identify a neighbor if it was within a range of 18” to 24”—a rather limited threshold. However, upon testing, it was observed that robots could be identified at distances ranging from 16” to as far as 40”. In switching from the previous banding method (see *Neighbor localization* in Chapter III), the physical height of the orange band had to be reduced, leading one to believe that perceived distances might suffer; however, distances remained consistent when the “faces” were implemented. This identification system provides great opportunity for further multi-robot coordination research (see *Multi-robot sandbox* in [Future Work](#) for details).

Software. The formation control algorithm was implemented in an extensive collection of libraries written and tested in Interactive C. Unfortunately, the use of this language was the greatest obstacle to progress. While IC, indeed, has a large population of users nationally for testing at the middle school and high school levels, more advanced programming concepts at the collegiate research level remain untested and buggy. A vast

majority of the time spent was on debugging the language itself, often necessitating undesirable workarounds (not fixes) and generating counterintuitive results.

It was discovered that, if a globally-defined character array (primarily serving the role as a communication buffer) exists with an odd number of elements and a serial command is used, that the system would freeze. Following suit, if an array is a member of some data structure, it would often crash the compiler. The built-in IC simulator had a tendency to produce results contrary to that of the hardware. For example, a programmer's intuition says—and the simulator validates—that if a long-integer were to exceed its maximum value, it would wrap around, becoming negative; however, when such a situation occurs on the XBC, the value is instead set to its maximum. Additional unexpected problems made even documentation difficult—if a certain combination of keys (often *Backspace* followed by a *Return*) is pressed while making multiple single-line comments in succession, the compiler will crash.

The bundled serial communication library, *xbcserial.ic*, provides basic functionality, but would occasionally cause the XBC to lock up. Effort was made to alleviate this, with minor modifications to the library that seemed to reduce—but not eliminate—the problem. For this reason, great care was taken to handle errors that could actually be detected in *Packet.ic* and *Communication.ic* (see Appendix B—Interactive C Code). Unfortunately, undetectable errors still would cause a system deadlock. This is likely the result of high network activity on a clearly untested serial communication system.

IC also offers support for multi-threading; however, it imposes extreme undocumented limitations that forced almost the entire algorithm to be re-implemented. It was observed that when a motor command was used in one thread and serial communication in another that erratic behavior would occur, such as the calling of the last function in a

random file or, more often, deadlock. This problem was circumvented (but by no means “solved”) by running the entire algorithm as single, sequential process. This drastically increased the amount of time for coordination. Robots would often pause for seconds at a time to process communicated packets while in the middle of other important operations, such as searching for neighbors or moving to correct for state errors. This would introduce a noticeable amount of error in the motion of the robot, as the dynamics of starting and stopping often introduced wheel slippage; however, the control algorithm demonstrated high fault tolerance and robustness, as robot movements would still produce the desired formation.

The worst limitation imposed by IC was that of program size, allowing only 48K of code to be transferred to the XBC (i.e., not a hardware limitation). Many of the software issues discussed required rather lengthy workarounds, reducing the amount of space available for actually implementing the algorithm itself. Preprocessor definitions were utilized to reduce the compilation of unused functions, but this was tedious and should not have been necessary. In the worst case, crucial components of the implementation had to be commented out in order to demonstrate, piecewise, certain aspects of the system.

For future implementations of the algorithm, a different language should be utilized.

Future Work

Dynamic neighborhoods

It has been shown that, as the formation changes, the neighborhood may change as well. In particular, consider a formation change in which the number of defining functions changes (for example, a straight line to a lattice). The current implementation of this work assumes that individual units have some sense of who their neighbors are supposed to be; however, if the robots are not initially put in a formation or the size of the neighborhood

changes, then a neighborhood must be established dynamically. This could be done using a market-based auctioning approach. A robot could begin an auctioning process, broadcasting the estimated formation-relative position of a neighbor if it were to meet a particular relationship. Upon receiving this message, nearby robots would decide to bid if they currently do not have a neighbor or if the auctioned formation-relative position is closer to p_{seed} than that of their own; a bid would take the form of a distance and orientation to the auctioning robot. The winner of the auction is the robot that minimizes the amount of work to establish the relationship. This would provide robustness in a system of imperfect and generic robots. If a robot exhibits failure and is removed from the formation, neighboring robots could dynamically reposition, so that the global integrity of the formation is maintained (see *Formation repair* for details). Periodically, new robots could be deployed that would add themselves to the edges of the formation for replenishment as needed. Neighborhood consistency must be attained, as some formations—such as branching and lattices—require that two cells share a common neighbor; in this case, a robot might only auction a relationship when those with its existing neighborhood are already established.

Seed election

When robots are initially scattered in an environment, selecting an optimal seed—one that minimizes the amount of time taken for messages and movements to be propagated—can be difficult. The current implementation of the algorithm has an operator designating a robot as the seed of a formation; however, an alternative approach would have the automaton elect a seed cell, which initiates communication with an operator. This would further promote the notion that this is a leaderless algorithm. McLurkin [18] observed that information in a distributed system is propagated and extracted fastest when it comes from the “center” (referring to the number of message hops, as opposed to physical distance) of the graph, but

leaves a distributed method for determining this “graph center” as future work. In the cellular automata approach, cells could append a “weight” to each “relationship path”—left and right relationships would then have associated with them a counter. In the case that no physical neighbor meets this relationship, the counter would be 0; however, if a relationship is established (perhaps via dynamic neighborhoods), then this counter would be set to the maximum of 1 (representing the neighbor) and the neighbor’s counter along the same path + 1. The cell with the most balanced “weight” along all paths would likely be the best candidate to be the seed. Presumably, the total number of robot units in the formation could be extracted from this counter information, which could be useful to a graphical user interface (described below in *Formation management*). Special consideration must be given to lattice formations, however, as cycles in neighborhoods might result in redundant counts.

Formation repair

In an ideal world, all robots would be “hyper-reliable”, consistently functioning without error; sensors would provide precise data, and robot effectors would masterfully interact with the world around it. Unfortunately, in the real world, this is not the case—sensors give imperfect or false readings, and effectors produce inaccurate manipulation due to the dynamics of the environment. For large-scale applications such as SSP [15], the likelihood of robot malfunction is extremely high. This same application places the formation of robots far from human hands, making system check-up and maintenance difficult. Therefore, it is crucial that the formation algorithm be fault tolerant. Suppose that a discrepancy in one or many neighborhoods is detected, revealing the failure of a group of robots. Gaps in the formation could be filled autonomously via the auctioning method for establishing neighborhoods; an error message could be sent to an operator to notify them of lost unit or units. In the case that the seed cell is among those in error, a new robot could be

promoted to this role using aforementioned seed determination algorithm. Of course, an immobilized robot becomes an obstacle to other robots attempting to find their place in the formation; thus, group obstacle avoidance is needed.

Formation obstacle avoidance

Currently, robots assume an obstacle free environment and safe movement action trajectories; however, real-world applications rarely place robots in such ideal conditions. Thus, a group obstacle avoidance system is needed such that the connectivity of the automaton is preserved where an obstruction is present, and parts of formation remain stable where an obstruction is not present. Suppose that a robot were to sense a barrier ahead; this robot could enter an avoidance mode, temporarily modifying its desired relationship to a neighbor that is not sensing the barrier (thus, presumably safe) such that it is oriented directly behind it. In the case that an entire neighborhood senses the obstacle, the robot would orient behind the neighbor that is closest to a cell that is obstacle-free—this is much like the relationship that a cell has to its reference neighbor. Upon passing the obstruction, the robots would assume their original relationships. Of course, this approach may only work for straight line or function-based formations; the physical complexity of multi-function formations may require a different kind of avoidance technique.

Global positioning

While simply producing a formation at some location is interesting, most applications of robot formations require them to be at some particular position and orientation in an environment. In this case, it would be appropriate to provide a seed cell with information about its absolute (as opposed to relative) pose, perhaps through GPS or overhead camera. This robot would move to correct any translational and rotational error between its current

and goal pose. Neighboring robots would still react using on only local information as the formation transforms to reach its final destination. This would also be useful in representing the formation in a graphical user interface (described below in *Formation management*).

3-dimensional formations

To fully explore the wide range of formations that can be represented by this algorithm, it must be modified to consider the 3-dimension. Note that 2-dimensional function-based formations can be abstracted as 1-dimensional cellular automata; likewise, some 3-dimensional formations can be abstracted as 2-dimensional cellular automata. The SSP reflector is a perfect example of this—a parabolic lens that can be expressed as a 2-dimensional network of robots. However, this is not always the case. Consider extending the square lattice definition into a series of functions that yield a cube formation; this type of structure can only be represented in 3-dimensions. For determining desired relationships, spheres could be used instead of circles to calculate function intersections. Motion control and formation manipulation would be extended, with translational and rotational error consider all three axes; likewise, a 6-degree-of-freedom robot platform, such as the SPHERES satellites [22], would be necessary to navigate in 3-dimensional space.

Disconnected formations

In the current work, the collective of all cell neighborhoods forms a fully connected automaton; however, consider a situation in which one or many cells are not part of any neighborhood in this particular automaton and, thus, not a part of the automaton at all. Separated by distance, obstructions, or even predetermined neighborhoods, these robots could begin the formation process independent of the other group—but, to do so, they must form their own automaton. All previous discussion now applies to both systems. A different

seed might be specified or elected for each formation and, consequently, each seed assumes communication with a human operator. How could an operator manipulate these disconnected formations? Presumably, each automaton would work to produce identical structures based on a common formation definition; however, different definitions could be given to each automaton such that two distinct formations are generated. In this case, it is actually appropriate for these formations to be separate. Likewise, could a formation be defined or bounded in such a way as to actually force a separation? Suppose these systems eventually come into contact. How would they react when neighborhoods are attempting to be resolved and a single seed is being elected? Conversely, could these formations be maintained separately, but defined such that one structure has a position and orientation relative to the other?

Formation classification

A preliminary classification of formations was presented earlier in this chapter; however, this classification is not exhaustive. It has already been noted that 3-dimensional formations yield interesting cases. Disconnected formations can produce two or more formations of different classes; if separate automata have relationships between them, recursive scenarios could even occur (i.e., one formation could be classified in one way, the other formation could be classified in another, and the relationship between them could have its own classification). Further study must be done to fully identify these categories—or perhaps a hierarchy—of formations.

Analysis

A series of experiments could be conducted and evaluated based on the criteria discussed in Fredslund & Mataric [10; Fig. 38] for reasons of comparison and analysis of the algorithm:

- *generality* – ability to conform to a variety of formations
- *stability* – ability to maintain the formation
- *robustness* – ability to respond to changes in group size
- *dynamic switching capability* – ability to respond to an operator’s command for changes in its organization

Fig. 38: Demonstrates Ability to Create and Maintain Different Formations:
 (a) Line, (b) Wedge, (c) Column, and (d) Diamond. [10]

While a formal study has not yet been performed, an estimate of performance can be postulated. It has been shown that the algorithm is extremely general, based on the stated formation classification, as well as the promise in future work to expand the list of formations attainable. Results in Tables (2 & 4) show that a formation remains stable once it has been established (note that Eq. 11 guarantees relationship stability). The algorithm is independent of the number of robots and is, thus, robust to group size; this can be actively demonstrated once a dynamic neighborhood method has been implemented. As seen in

Chapter III, an operator can quickly and easily manipulate a formation in a variety of different ways.

Formation management

In multi-robot management, little work has been done in terms of a human-robot interface for formations. Skubic *et al.* [26] implemented an impressive sketch-based interface via Personal Digital Assistant and global communication to control a small team of mobile robots already in formation [Fig. 39]. This proves to be inadequate for SSP, and thus an original interface must be designed and created for the control of large robotic formations.

Fig. 39: An Operator Sketches Movement Commands to a Formation of Three Robots to Move Forward (Left) and Strafe Right (Right). [26]

To manage the robot formation, a graphical user interface could be developed that would provide a human operator with a visualization of the formation and information of each individual robot unit. Through the interface, the operator would be able to choose the seed robot to instigate a change in the formation.

Multi-robot sandbox

The robot platform presented provides a variety of tools that can be used to implement and test various multi-robot systems. While homogeneous in terms of hardware, unique physical identifiers combined with addressed communication allow for heterogeneous applications. To keep with a theme of this work, consider a physical implementation the most well-known example of cellular automata, Conway's Game of Life [29]. To be consistent, let The Game be represented as a Class I swarm in a 2-dimensional robot-space cellular automaton (note that this could also be represented in world-space). A cell neighborhood could consist of all cells within the automaton, with relationships—and not the cells themselves—in a state of “alive” or “dead”; strict rules, based on the states of these relationships, would dictate robot actions, producing interesting emergent behavior. The platform serves as a “sandbox” for multi-robot creativity—the possibilities are endless.

Publications and Recognition

This work has received considerable attention in the academic and professional communities, warranting publications, presentations, grants, and awards.

APPENDIX A
SIMULATOR CODE

Behavior.cpp

```

//
// Filename:      "Behavior.cpp"
//
// Programmer:    Ross Mead
// Last modified: 04Sep2006
//
// Description:   This class implements a robot behavior.
//

// preprocessor directives
#include <cmath>
#include "Behavior.h"
using namespace std;

// <constructors>

//
// Behavior(s, t, r, speed)
// Last modified: 04Sep2006
//
// Default constructor that initializes
// this behavior to the parameterized values.
//
// Returns:      <none>
// Parameters:
//     s         in         the status of the behavior (default INACTIVE)
//     t         in         the translational velocity of the behavior (default 0)
//     r         in         the rotational velocity of the behavior (default 0)
//     speed     in         the maximum speed of the behavior (default 1)
//
Behavior::Behavior(const Status s,
                  const GLfloat t,
                  const GLfloat r,
                  const GLfloat speed)
{
    setMaxSpeed(speed);
    setVelocity(t, r);
    setStatus(s);
} // Behavior(const Status, const GLfloat, const GLfloat, const GLfloat)

//
// Behavior(beh)
// Last modified: 27Aug2006
//
// Copy constructor that copies the contents of
// the parameterized behavior into this behavior.
//
// Returns:      <none>
// Parameters:
//     beh       in/out     the behavior being copied
//
Behavior::Behavior(const Behavior &beh)
{
    *this = beh;
} // Behavior(const Behavior &)
