

Research Statement

My research interests focus on the development and validation of models of recovery in individuals with chronic disabilities using novel technologies, including wearable sensors and assistive robotics. My previous research has developed signal processing and machine learning algorithms to extract clinically meaningful measures of human performance from multimodal biological data for use in monitoring and augmenting behavior and performance in ambient environments. **The central motivating theme of my research is ambient assisted living: the use of assistive technologies in real-world settings outside of clinical or laboratory environments to assist people living with disability.**

Demographic population changes have led to more people aging into and with disability, placing an increasing burden on society. However, there is currently a lack of evidence pertaining to key determinants of outcomes after treatment, and the time course of chronic conditions. Targeted use of assistive technologies will help to bridge this knowledge gap, but will require (1) technical expertise to develop computational tools to understand relevant physiological data and (2) the practical understanding of the needs of end users, including patients and clinicians, required to translate research outcomes to practice. My predoctoral and postdoctoral research has provided me with strong, cross-disciplinary expertise in mechanical and electrical engineering, computer science, motor-neurorehabilitation, physical therapy, and movement science. I will leverage my skills to create novel techniques for understanding biological signals in order to aid in the development of interventions to improve quality of life, and to translate research findings to individuals living with chronic conditions.

Predocctoral and Postdoctoral Research

Home-based health monitoring is a novel approach to healthcare for the elderly and others with chronic disabilities. My doctoral research at MIT focused on lightweight wearable systems for such monitoring. My research incorporated mechanical design, human factors, smart materials, and electromechanical modeling techniques in the development of a novel wearable powerline communication network for physiological monitoring that simultaneously transmitted data and power over a shared medium [J5]. I developed and validated an electrical equivalent model of the transmission modem and medium composed of lightweight electrically conductive fabric (ECF), modeled its power transmission characteristics using finite element analysis, and validated the models using simulations and experiments. The system was used to transmit body pose data over the wearable sensor network and established guidelines for the design of ECF garments; it was also the first application of ECF as a local power and data transmission medium [J4].

During my postdoctoral fellowship at USC, I continued working on wearable sensing, in the domain of human robot interaction (HRI) for stroke rehabilitation. I developed an inertial measurement unit (IMU) and data analysis algorithms for measuring human motion (Figure 1a) [C12]. To validate the algorithms, I compared sensor measures to subtasks of the Wolf Motor Function Test (WMFT), a standard assessment of functional activity after stroke (Figure 1b). By combining IMU and video camera data, I obtained estimates for both the timing and functional ability scores of the WMFT using a Naïve Bayes classifier and clinician rated scores [C10, C11]. In addition, I developed a gesture recognition technique for the IMU data using Hidden Markov Models (HMM). To discriminate between rehabilitation task inspired gestures, I segmented IMU motion data using overlapping time windows and computing the Fourier coefficients of the resulting signals. The use of these classifiers in conjunction with motion data can be extended to continuous activity monitoring for tracking people's behavior in the home environment, and developing measures of long-term recovery.

Moving beyond assessment, wearable sensing can be used to investigate human performance during therapeutic interventions. My postdoctoral work included the use of the IMUs in a robot-based therapeutic task practice system for individuals poststroke (Figure 1c) [J2, C3-5]. This socially assistive robotic

(SAR) system has been used to elicit health promoting outcomes in various user populations. Our studies investigated the influence of robotic behaviors (verbalization and gestures) on the user, and quantitative measures of performance based on wrist motion data. The framework was used to autonomously guide task practice in clinical environments, which can lead to the provision of rehabilitation for individuals who no longer have access to care through their healthcare provider. My ongoing research is investigating the effects of robot behaviors (through the provision of various types of feedback) on user kinematics and psychosocial state to facilitate participant self-efficacy after stroke onset.

I next investigated the validity of wearable sensors for capturing kinematic measures of performance in ambient environments [J1]. Kinematic data regarding motor performance changes provide insight into recovery after stroke. I have utilized spectral analyses of accelerometer data to predict known kinematic measures of motor control and efficiency that do not rely on *a priori* gesture segmentation. By comparing signal power in various frequency bands, I quantified measures of performance from wrist motion data. The availability of these novel kinematic measures will allow us to better understand the time course of motor changes after stroke, providing greater insight into the mechanisms of upper extremity stroke recovery outside of laboratory and clinical settings, thereby informing the development of future interventions.

Future Research

I will establish an academic research laboratory focused on the development of methodologies that make use of wearable sensors and robotic systems to investigate changes in motor control, learning, and performance in individuals with chronic conditions, including the aging and disability populations. I will use the skills acquired during my predoctoral and postdoctoral training to target improvement of participant centered quality of life through technology driven applications. Knowledge of the ways in which individuals behave in various contexts will illuminate how they perceive their capabilities, whether and how they engage in meaningful activities, and how they optimize participation in home and community life; it will also allow for better formulations of interventions and evidence-based rehabilitation strategies. I will also use wearable sensors and personal robotic systems to both validate and inspire theoretical models of motivation, rehabilitation, and the re-integration of these individuals into their communities.

The following systematic approaches, well aligned with recent funding initiatives by the National Institutes of Health and the National Science Foundation to promote the translation of research findings to the scientific and clinical communities, will be used:

Capturing long-term performance changes – Temporal changes in motor performance may serve as “biomarkers” for the potential progression of chronic conditions. For instance, the effects of aging, nonuse of the hemiparetic limb after stroke, and responses to Parkinson’s Disease medication may result in unique

motor characteristics that change over various time periods. At the moment, no tools exist to capture the changes in performance that occur longitudinally over time after the onset of a chronic condition, or after an intervention is completed. In order to develop models of these processes, we need objective observations of how individuals progress during their recovery in real-world settings. I will use the spectral analysis measures developed during my postdoctoral fellowship to longitudinally track outcomes of treatments, which will lead to evidence derived models of people's responsiveness to therapeutic interventions. Spectral and kinematic measures can be captured and quantified for epochs of wearable sensor data. I will use the time evolution of these parameters to characterize behavioral models of change and recovery in response to specific changes in condition (such as the development of compensatory movements after stroke onset).

Optimizing task practice – Challenging, dynamic, task specific practice is necessary for recovery after a brain injury. During rehabilitation, the interactions of the user's psychological and mental state with practice variables (e.g., provision of feedback, knowledge of results, schedules of practice, contextual interference, practice dose) will determine the efficacy of the intervention. I will investigate the use of these interactions to elicit clinically meaningful outcomes in individuals poststroke using a SAR framework. I will develop robot control schemes that dynamically respond to a model of user state generated from the application of dimensional reduction techniques to multimodal physiological and performance data. Such a system will provide a user specific challenge level that adapts to user performance in real-time to optimize learning. The SAR framework will be capable of controlled manipulation of practice variables, which will yield insights into the role of these variables in therapeutic interventions.

Remotely administered assessments – For chronic conditions, objective evaluation of functional ability through the use of standardized functional assessments is necessary to understand long-term changes in ability. Such assessments are typically administered by trained clinicians, and are thus infeasible once patients have left the rehabilitation setting. To close the knowledge gap created by the lack of standard measures of performance outside of clinical settings, I will develop tools for the administration of standard functional assessments in the home setting. I will extend my postdoctoral work to utilize supervised learning on multimodal sensor data to classify performance according to human rated scores. Using both existing devices, and new devices I will develop, I will establish the validity and determine the clinical significance of quantitative sensor measurements of user state in predicting outcomes of standardized functional assessments. This will allow individuals to self administer assessments in the home environment, for real-time and offline evaluation by health professionals.

The goal of engineering for health science research is to develop new methodologies that take advantage of the power of data driven research. This requires the incorporation and integration of quantitative engineering techniques, quantitative social science research, and interdisciplinary research teams that use a variety of tools to solve complex health problems. Through the use of quantitative motion data, spectral analyses, learning algorithms, and theoretical underpinnings of disability, outstanding research questions in aging and disability can be approached with methodological, inference driven methods. With my interdisciplinary training in engineering and healthcare, I am uniquely suited to address novel problems in this emerging field.
