

snlp_parser

by Gregory Koch (gkoch09@austincollege.edu)

Last revision: *August 3, 2011*

The **snlp_parser** package consists of a single ROS node that uses a TCP client together with a Java server to take in a string from any component of Bandit and return a complete NLP data structure containing relevant part-of-speech information using the Stanford NLP parser.

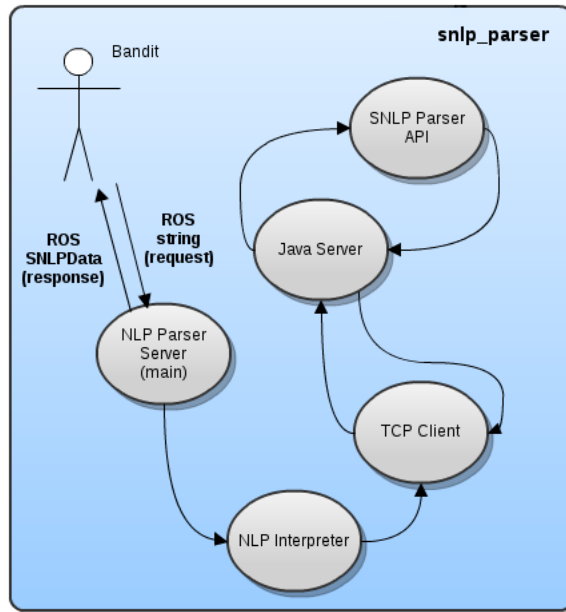

1 General

- All of the necessary files for **snlp_parser** can be found in the ROS package of the same name.
- The **dragon_sr** package is divided into two portions: Java and C++, respectively.
- The Java portion contains three files in the java directory: the grammar folder, containing the English grammar information for the Stanford NLP parser, `ParserServer.java`, and `stanford-parser.jar`. These files provide the Stanford NLP functionality along with the implementation of the Java server that accesses the parser.
- The C++ portion is composed of several files: `NLPInterpreter.cpp`, `NLPInterpreter.h`, `nlp_parser_client.cpp`, `nlp_parser_server.cpp`, `tcp_client.cpp`, and `tcp_client.h`. The main class is `nlp_parser_server.cpp`, used to set up ROS server functionality and also convert the C++ NLP data structure to an equivalent ROS data structure. The `nlp_parser_client.cpp` component also contains a main function, and can be used as a demo of how to connect **dragon_sr** to `nlp_parser_server.cpp`. Finally, `NLPInterpreter.cpp` and `tcp_client.cpp` are used for data structure building and TCP functionality.
- The package also contains **srv** and **msg** files for ROS to facilitate data transfer for parsing information. Please see the sections entitled **SRV Files**, **MSG Files**, respectively, for detailed information on these new data types.

2 Approach

- Excluding the functionality of the demo program, `nlp_parser_client.cpp`, for interfacing with **snlp_parser**, the behavior of the code contained in the **snlp_parser** package begins in the main function of `nlp_parser_server.cpp`.
- The first responsibility of `nlp_parser_server` when it initializes itself is to spawn the Java server that directly accesses the Stanford NLP parser on a free port within its own thread.
- Once that is complete, the program proceeds to initialize ROS and begin the **snlp_parser** service on the main thread of execution.
- This service is initialized with a callback function, `messageReceived`, which is called whenever the server receives a message from any client containing the string to be parsed by the Stanford NLP parser.
- The first call in this callback function sends its text request to the `NLPInterpreter` in `NLPInterpreter.cpp`. The function then blocks, waiting until input has been received back from the `NLPInterpreter`.
- The `NLPInterpreter` passes this text input down into the `TCPCClient`, which connects on Java server's port to pass it the data to parse.
- The Java server uses the text it receives along with the Stanford NLP API to return a string of parsed data to the `TCPCClient`. Each different portion of the NLP data is enclosed in certain tags: `<text>` tags for the original string itself, `<blbs>` for the part-of-speech tags, `<tree>` for the parse tree, and `<depd>` for the dependency graph.
- The `TCPCClient` puts any data it receives into a queue, which is continually being checked by the `NLPInterpreter` in its thread's main loop (see function `interpreterMainLoop` in `NLPInterpreter.cpp`).
- Once the `NLPInterpreter` gets a response out of the queue, it calls the `handleSNLPData` function on that response.
- The `handleSNLPData` function consists of a large FSM designed to turn the text version of the NLP data into a convenient data structure. The function will return a pointer to this new `SNLPData`, which is subsequently placed into a queue of `SNLPData*` type.

- Once this queue is non-empty, the `nlp_parser_server` function call will unblock, get the pointer from the queue, and use it to setup an identical data structure to the one just created in `handleSNLPData`, but using only ROS types.
- Finally, the memory used for the `SNLPData` object is released, and the ROS version of the NLP data object is returned as the response by the `ros::ServiceServer`.
- For an abstracted view of this process, see the figure below:

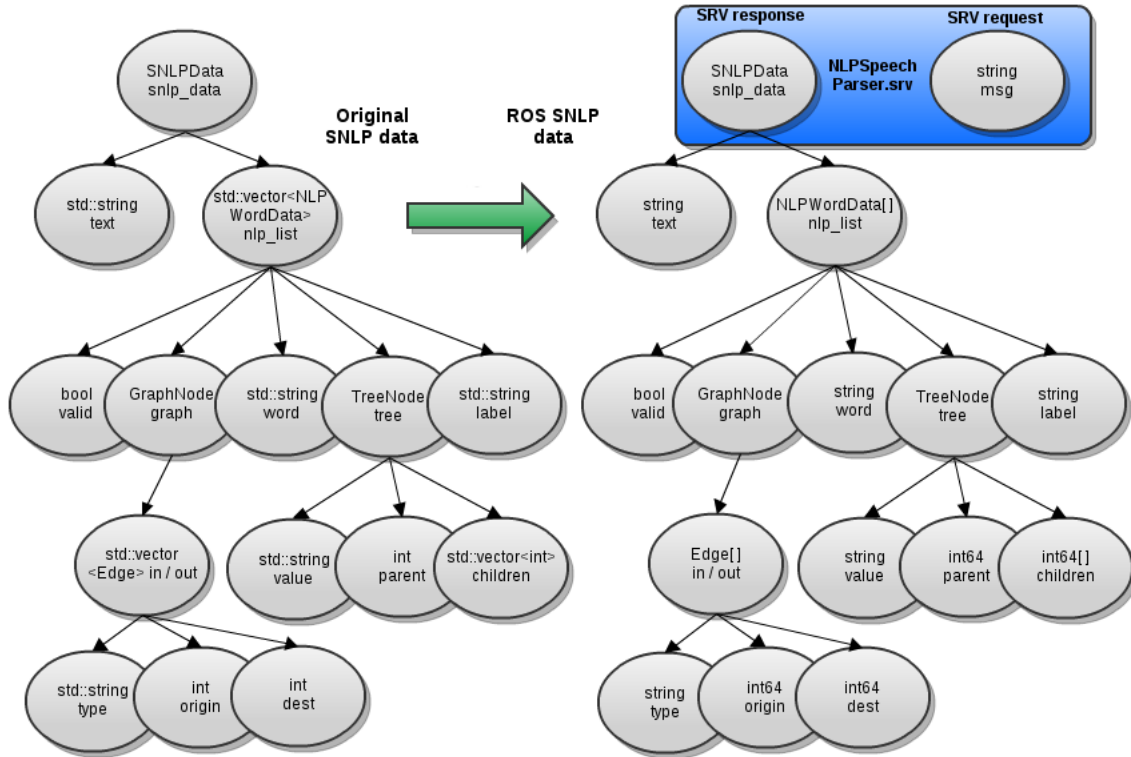

3 SRV Files

- The `snlp_parser` package uses one `SRV` file to facilitate communication between the NLP server (`nlp_parser_server.cpp`) and a NLP client using ROS, defined in `..\snlp_parser\srv\NLPSpeechParser.srv`.
- The request consists of a single ROS string, `msg`, which is equivalent to a C++ string.
- The response consists of a custom data structure defined through a series of `MSG` files (see next section). The top level structure is `snlp_data` of type `SNLPData`.
- **Note:** to use `NLPSpeechParser.srv`, `roscpp_gensrv()` must be included in `CMakeLists.txt`. This will automatically generate relevant files used by ROS to support the `SRV` file.

4 MSG Files

- The `snlp_parser` package uses five `MSG` files to facilitate communication between the NLP server (`nlp_parser_server.cpp`) and a NLP client using ROS, defined in the `..\snlp_parser\msg` directory.
- The highest level `MSG` file is defined in `SNLPData.msg`, which defines a string which should contain the original text generated by Dragon *NaturallySpeaking* in the speech recognition step using the microphone. It also defines a vector of type `NLPWordData`, which holds all of the word data for the input phrase corresponding to the original vector generated by the `NLPInterpreter` object.
- The next level of `MSG` file is defined in `NLPWordData.msg`. This file defines five components: a `bool` corresponding to whether the word data represents an actual word in the phrase or tree data, the word itself, the NLP tag for the word, if applicable, and the graph and tree nodes for the word. Their purposes are likewise analogous to the original data structure. Because this holds for the remainder of the `MSG` files in the directory, we present a diagram showing the mapping from the NLP data structure defined in `NLPInterpreter.h` and the hierarchy of `SRV` and `MSG` files used in `snlp_parser` to communicate between components with ROS:

- **Note:** to use the MSG files, `roscpp_genmsg()` must be included in `CMakeLists.txt`. This will automatically generate relevant files used by ROS to support the SRV file.

5 Interfacing with `snlp_parser`

- Communicating between another ROS node and the `snlp_parser` package is not difficult, but requires an understanding of ROS client/server mechanisms, as well as SRV and MSG files. Please see the previous two sections for more information.
- We will use `nlp_parser_client.cpp` as an example to show how to send and receive messages with `snlp_parser`.

Listing 1: Main function

```
int main(int argc, char **argv){
    ros::init(argc, argv, "nlp_parser_client");
    if (argc != 1)
    {
        ROS_INFO("usage: nlp_parser_client");
        return 1;
    }
    ros::NodeHandle n;
    client = n.serviceClient<snlp_parser::NLP SpeechParser>("snlp_parser");
    ros::Subscriber sub = n.subscribe("mic_data", 10, speechCallback);

    ros::spin();

    return 0;
}
```

- In the main function, we first initialize the ROS node under the name `nlp_parser_client`, then set up a node handle and use that handle to initialize our `ros::ServiceClient` client, which is declared globally to give us access to it in our callback function. This client will be responsible for communicating with the corresponding server on the other end, `nlp_parser_server.cpp`.
- Next, we initialize our subscriber, which is responsible for checking for incoming microphone data. The subscriber is initialized to listen to the publisher `mic_data`, created in the package `dragon_sr`. The subscriber is given a maximum

queue size of 10, as well as the callback function `speechCallback`, which is called by ROS whenever the subscriber receives an incoming message containing a string of data generated by Dragon *NaturallySpeaking*.

- Finally, we tell ROS to spin, so that we can begin checking for callbacks.

Listing 2: Client callback function

```
void speechCallback(const std_msgs::String::ConstPtr& msg)
{
  ROS_INFO("Input speech data: [%s]", msg->data.c_str());
  nlp_parser::NLPSPeechParser srv;
  srv.request.msg = msg->data;
  if (client.call(srv)){
    ROS_INFO("NLP speech data: %s", srv.response.nlp_data.text.c_str());
    printNLPData(srv);
  }
  else{
    ROS_ERROR("Failed to call service nlp_parser");
  }
}
```

- In the callback function, we want to forward any new microphone data received from `dragon_sr` to the NLP server for further processing by the Stanford NLP parser.
- Doing this is fairly simple. We first create a new `NLPSPeechParser` of type `SRV` defining the message type to send via ROS to `nlp_parser_server.cpp`. We then take the received data `msg.data` and put it in the `SRV` file as the `MSG` to send.
- Finally, we make the blocking call `client.call(srv)`, which sends the `srv.msg` to the server, and returns when the server provides `srv.response`.
- We use an optional custom printing function to check the contents of the NLP data structure upon receipt. From here, the NLP data could be placed inside a queue for further processing, or otherwise sent to the module of your choice depending on your robot's configuration.

6 Compiling

- Open the Linux terminal and run the command `rosmake nlp_parser nlp_parser` from any directory on any computer containing the `nlp_parser` package. This will compile `nlp_parser_server.cpp` and all its non-Java derivatives (`NLPInterpreter.cpp` and `tcp_client.cpp`), as well as the demo program `nlp_parser_client.cpp`. Compiling `nlp_parser_client.cpp` can be disabled by editing `CMakeLists.txt` in the `nlp_parser` ROS package.
- To recompile the Java server code that interfaces with the Stanford NLP API, go to the directory `..\nlp_parser\java` and run the command `javac -cp stanford-parser.jar ParserServer.java`.
