

Multiple Objective Behavior-Based Control

P. Pirjanian

USC Robotics Research Laboratory, Department of Computer Science, University of Southern California, Los Angeles, CA 90089-0781

Abstract

The notion of optimality and its feasibility are revisited in the context of behavior-based control. It is argued that optimal behavior is not feasible for real-world applications. As an alternative to optimality I promote *Pareto-optimal* and *satisficing* solutions which correspond to efficient and ‘good enough’ behavior. It is then demonstrated that *multiple objective decision theory* provides a suitable framework for formulating behavior-based controllers that generate Pareto-optimal and satisficing behavior. A set of simulated and real-world experiments are reported that support this view.

Key words: action selection, behavior-based control, satisficing behavior, Pareto-optimality

1 Introduction

In real-world robotics it is not feasible to aim for *optimal* control even if an optimal strategy should exist, because unstructured environments are unpredictable, robotic sensors and actuators are imperfect, and computational and other resources (such as response time) are sparse. It is thus more appropriate to search for control strategies that in practice are *efficient* and *sufficiently satisfying*, i.e., ‘good enough’ rather than optimal. This in fact has been an implicit agenda in behavior-based robotics all along. However, the view taken in this paper is that only by having this as an explicit goal can we hope to produce behavior that is ‘good enough’. In the behavior-based approach there are no centralized planning modules that search for plans with some optimality criteria (e.g., shortest path, safest path, or minimal power consumption). Rather, control in behavior-based robotics is shared between a set of perception-action units, called behaviors, where each behavior is responsible for one specific aspect of control (such as obstacle avoidance, target following, door traversal etc.) in isolation from the other behaviors. Note that a solution

that is simultaneously optimal with respect to all the behaviors might not exist due to conflict between behavioral objectives. The optimization of one behavior's objective might be associated with a simultaneous deterioration of other behaviors' objectives. Thus a major issue in behavior-based control is to formulate strategies that can guarantee a suitable trade-off between a multitude of (potentially) conflicting behavioral objectives. This is known as the action selection or behavior coordination problem.

Action selection mechanisms (ASMs) can be divided into two main groups known as *arbitration* and *command fusion*, respectively. *Arbitration* mechanisms are suitable for behavior selection, i.e., the activation of the set of behaviors that is relevant in a given context. Examples of arbitration mechanisms include the Subsumption Architecture [2], Discrete Event Systems [5], and activation networks [6]. *Command fusion* mechanisms on the other hand are suitable for coordination of the activities of the set of behaviors that are active simultaneously in a given context. These include the Payton-Rosenblatt voting approach [8], fuzzy command fusion mechanisms (see [9]), potential-fields methods [1], the dynamic systems approach [10], and finally multiple objective action selection introduced in this paper. A key feature of multiple objective action selection is that it provides an explicit definition of optimality that is both suitable and practical for behavior-based robotics.

The view promoted in this paper is that behavior-based control strategies should *explicitly* define a notion of optimality that is both suitable and practically feasible for the kind of problems that it is trying to solve. Only then will it be possible to specify and design systems that can generate efficient and 'good enough' behavior. In this paper, a notion of optimality for behavior-based control is proposed and used to formulate a class of action selection mechanisms called Multiple Objective Action Selection Mechanisms (MOASMs). Acknowledging the fact that optimal actions might not exist due to conflicting objectives, MOASMs seek for *satisficing* actions, i.e., actions that *satisfy* each objective function to a *sufficient* degree. I postulate that satisficing actions comprise 'good enough' actions in the action selection problem.

2 Introduction to Multiple Objective Decision Making

The introduction given in this section will focus on aspects of multiple objective decision making that are relevant to the subsequent discussion of action selection mechanisms. For complementary reading on this subject please refer to [3].

Multiple objective decision making (MODM) provides approaches to making decisions in situations where more than one decision objective should be con-

sidered. Traditional optimization techniques are inadequate for solving problems where more than one decision objective should be considered. Improvement in one objective might be associated with a deterioration of another, in cases where the objectives are competitive and conflicting. Mathematically, a multiobjective decision problem can be represented in the following way:

$$\begin{aligned} \max_{\mathbf{x}} \quad & [o_1(\mathbf{x}), o_2(\mathbf{x}), \dots, o_n(\mathbf{x})] \\ \text{subject to} \quad & \mathbf{x} \in X, \end{aligned} \tag{2.1}$$

where $\mathbf{x} = (x_1, \dots, x_N) \in R^N$ is a N-dimensional decision variable vector or alternative. The system objectives or criteria are represented by n objective functions, o_1, \dots, o_n . The degree of attainment by a particular alternative \mathbf{x} , with respect to the k th objective is given by $o_k(\mathbf{x})$. $X \subseteq R^N$ defines the set of *feasible* alternatives. This problem is in the literature often known as the Vector Optimization Problem (VOP).

Since optimal solutions might not exist one can only hope for solutions that *satisfy* each of the objectives to a *sufficient* degree. This idea is encompassed in the following definition.

Definition 2.1 (A Satisficing Solution) *A satisficing solution of Simon[11] extended to a VOP is a reduced subset of the feasible set, which exceeds all of the aspiration levels (goals) of each objective.*

Simon points out that it might be impractical to search for an optimal solution due to certain limitations. He thus argues that in practice it is more efficient to look for solutions that are ‘good enough’. A satisficing solution corresponds to the behavior of a decision maker who looks for ‘good enough’ solutions. Another useful notion of optimality in the context of multiple objective decision making is *Pareto-optimality*.

Definition 2.2 (A Pareto-Optimal Solution) \mathbf{x}^* *is a Pareto-optimal solution to a VOP iff there does not exist any $\mathbf{x} \in X$ such that $o_i(\mathbf{x}^*) \leq o_i(\mathbf{x})$ for all i and $o_j(\mathbf{x}^*) < o_j(\mathbf{x})$ for at least one j .*

Intuitively, a Pareto-optimal solution is one in which no other solution can improve one objective function without a simultaneous deterioration of at least one of the other objectives. A Pareto-optimal solution is also known as a nondominated solution, a noninferior solution, or an efficient solution. Thus based on a subjective judgment of the objective function values it is possible to exclude the set of alternatives that are obviously not efficient or Pareto-optimal. Apart from excluding inefficient solutions, this process significantly

reduces the number of alternatives which simplifies the subsequent search for satisficing solutions.

2.1 Solving vector optimization problems

The procedure for solving vector optimization problems proceeds in three steps:

- (1) **Pareto-optimal solutions:** Generation of Pareto-optimal solutions based on the objective functions.
- (2) **Satisficing solutions:** Generation of satisficing solutions that best achieve some appropriate goal or aspiration level for each objective.
- (3) **Preferred solution:** Selection of one satisficing solution that is Pareto-optimal and most preferred.

The first step is carried out by objective evaluation of the alternatives against system objectives and then selecting the alternatives that are not dominated. In steps two and three, the decision maker's preference structure is incorporated in the form of weights, priorities and goals to express the importance of objectives relative to others. Then among the set of nondominated solutions, a solution is selected that best reflects the preference structure expressed in terms of weights etc.

2.2 Generating Pareto-optimal solutions

Numerous approaches exist to generating Pareto-optimal solutions, however, in the context of action selection we are interested in approaches that have practical application. The *weighting* approach is an effective method that is based on scalar vector optimization and is formulated in the following way: $\hat{\mathbf{x}} = \underset{x \in X}{argmax} \sum_{i=1}^n w_i o_i(\mathbf{x}) = \mathbf{w}^T \mathbf{o}(\mathbf{x})$, where w_i are weights normalized so that $\sum_{i=1}^n w_i = 1$. According to theorem 4.6 in [3], we can claim that $\hat{\mathbf{x}}$ is a Pareto-optimal solution if $\hat{\mathbf{x}}$ is a unique solution or if $w_i > 0$ for all i .

2.3 Generating satisficing solutions

In order to go beyond merely generating Pareto-optimal solutions, some techniques incorporate the decision maker's subjective preference structure to identify satisficing alternatives among those that are Pareto-optimal. In the approaches presented here the DM's preference structure is usually expressed in

many forms including, *weights, priorities, goals, and ideals*. In this paper there is room to mention merely a few approaches. See [7] for further reading.

2.3.1 Lexicographic method

In the lexicographic method it is required to rank order the importance of all objectives. Assume that the objectives are ranked in decreasing order of importance, o_1, o_2, \dots, o_n . Then a sequential elimination process is started by solving the following sequence of problems until either a unique solution is found or all the problems are solved:

$$\begin{aligned}
 P_1 : \max_{\mathbf{x} \in X} \quad & o_1(\mathbf{x}), \\
 P_2 : \max_{\mathbf{x} \in X_1} \quad & o_2(\mathbf{x}), \\
 & \dots \\
 P_i : \max_{\mathbf{x} \in X_{i-1}} \quad & o_i(\mathbf{x}), X_{i-1} = \{\mathbf{x} | \mathbf{x} \text{ solves } P_{i-1}\}, i = 2, \dots, n + 1.
 \end{aligned} \tag{2.2}$$

The basic idea is that the first objective is used to screen the solutions of the second objective and so on.

2.3.2 Goal programming

In *goal programming methods* the DM gives his/her preferences in terms of weights, priorities, goals, and ideals. The concept of *best alternative* is then defined in terms of how much the actual achievement of each objective deviates from the desired goals or ideals. Goal programming methods thus “*choose an alternative having the minimum combined deviation from the goal $\hat{o}_1, \dots, \hat{o}_n$, given the weights or priorities of the objective functions*”, [3, page 302]. The general formulation of this multiobjective decision problem is known as the surrogate multiobjective decision problem (MDP).

$$\begin{aligned}
 \min_{\mathbf{x} \in X} \left\{ d_p(\mathbf{o}(\mathbf{x}), \hat{\mathbf{o}}) \triangleq \left(\sum_{j=1}^n w_j |o_j(\mathbf{x}) - \hat{o}_j|^p \right)^{1/p} \right\} \\
 \text{subject to } \mathbf{x} \in X,
 \end{aligned} \tag{2.3}$$

where $1 \leq p \leq \infty$, $\hat{\mathbf{o}}$ is the goal vector, w_j is the weight or priority given to the j th objective, and $d_p(\cdot, \cdot)$ represents the l_p norm ‘distance’ between $\mathbf{o}(\mathbf{x})$ and $\hat{\mathbf{o}}$. Once the goal, $\hat{\mathbf{o}}$, and weights or priorities, $\mathbf{w} \triangleq (w_1, \dots, w_n)$, are given, and (2.3) is formulated for any appropriately chosen value of p then solutions of the equation determine compromise solutions. The solutions of equation (2.3) may not be nondominated, only when $\hat{\mathbf{o}} = (o_1^*, \dots, o_n^*)$ where $o_j^* = \max_{\mathbf{x} \in X} f_j(\mathbf{x})$ and either the solution is unique or $w_j > 0$ for each $j = 1, \dots, n$ is a solution of equation (2.3) nondominated.

3 Multiple Objective Action Selection

In the behavior-based spirit a complex control problem is divided into a set of control problems that are simpler to solve. This corresponds to the breakdown of complex tasks into specific objectives. In this way we can relate behaviors to objectives. Further, action selection corresponds to finding satisficing solutions to multiple objective decision making problems. Establishing this link between behavior-based control and multiple objective decision making is the key to formulation of *multiple objective action selection* which proceeds in the following steps:

Design of behavior repertoire: Given system specification and task requirements, formulate a set of specific objectives, o_1, \dots, o_n and associated measurable attributes that are indicative of the degree of achievement of the corresponding objectives. Each objective is implemented by a behavior and hence the objectives define the behavior repertoire necessary for the given system (task).

Design of behaviors: Each objective function o_i is modeled as a behavior b_i that assesses the attribute values of that objective. Thus behavior b_i is responsible for maintaining the i th objective, o_i . The assessment of the attribute values by a behavior can be based on any appropriate method.

Action selection: From the set of alternative actions, X , we select actions that are Pareto-optimal **and** satisficing solutions to the vector optimization problem in equation (2.1), where the objective functions o_1, \dots, o_n are the ones identified in step 1 and implemented by behaviors b_1, \dots, b_n in step 2.

4 Mobile Robot Navigation Example

In this section we demonstrate the principles of the proposed approach, by considering a fairly simple example; namely the mobile robot navigation example consisting of three objectives. The parameters chosen for controlling the mobile base are the translation velocity v and the angular velocity ω , i.e., $\mathbf{x} = (v, \omega)$.

4.1 Behaviors

The objective functions identified in the previous section should be defined for a feasible set of alternative actions. The actions that we consider are control parameters for the mobile robot. In order to simplify the implementation of the behaviors to achieve efficiency we assume that the trajectory of the robot

Fig. 1. (a) Move fast forward objective function. (b) Move to target objective function. (c) Avoid obstacle objective function. (d) In this case the robot environment is as depicted in figure. \ominus represents the robot and $+$ represents the target.

can be approximated with piecewise circular arcs [4]. Such a circular trajectory is uniquely determined by its radius and is defined as the ratio of the translational and angular velocities, i.e., $r = v/\omega$.

Move fast forward This is the simplest of the behaviors and its objective is to make sure that the robot achieves its task as fast as possible. The objective function can be formulated as a linear function of the translation velocity, $b_{mff}(v, \omega) = a \frac{v}{v_{max}} + b$, where a and b in our case are chosen to be 1 and 0, respectively. The objective function is further normalized and its values are in the interval $[0, 1]$. Figure 1(a) is a plot of this objective function over discrete values of v and ω .

Maintain target heading The move to target behavior has the objective to move the robot towards a given target position, $b_{mh}(v, \omega) = \frac{1}{1 + \left(\frac{\theta_{pred}(v, \omega) - \theta_{target}}{\beta} \right)^2}$, where $\theta_{pred}(v, \omega) = \theta_0 + \omega T$ is the predicted robot heading for control parameters (v, ω) , θ_0 is the current robot heading and T is the time-constant determined by command generation frequency. A plot of the objective function is depicted in figure 1(b).

Avoid obstacle The objective of this behavior is to move the robot at a safe distance from obstacles. Sonar range readings, provided by the sonar ring, are used to detect obstacles. Then the obstacle avoidance behavior calculates for each path determined by the pair of control parameters (v, ω) the shortest distance to the obstacles on its path. Formally the objective function is given by: $b_{ao}(v, \omega) = \min\{Far(d) | d = dist(v, \omega, o) \forall o \in Obs\}$, where $Far : R \rightarrow [0, 1]$ is a S-function that maps the distances into the interval $[0, 1]$. Obs is the set of detected obstacle positions $o = (x, y)$ and

$$dist(v, \omega, o) = \begin{cases} \frac{v}{\omega} \gamma & \text{if } \omega \neq 0 \text{ and } (x - x_o)^2 + (y - y_o)^2 = \left(\frac{v}{\omega}\right)^2; \\ \sqrt{x_o^2 + y_o^2} & \text{if } \omega = 0 \text{ and } x = 0; \\ \infty & \text{otherwise,} \end{cases} \quad (4.1)$$

$c = (x_0, y_0)$ is the center of the circular path and γ is the angle between the line from c to robot position and the line from c to o . Figure 1(c) is a plot of the objective function for the example depicted in figure 1(d). Note that the objective function expresses the desire to make a sharp left or right turn (in order to avoid the obstacle).

4.2 Action selection

Action selection for the set of behaviors designed in the previous section can be formulated as the following vector optimization problem: $\max_{\mathbf{x}} [o_{ao}(\mathbf{x}), o_{mh}(\mathbf{x}), o_{mff}(\mathbf{x})]$, subject to $\mathbf{x} \in X$, where o_{ao} , o_{mh} and o_{mff} are objective functions estimated by behaviors b_{ao} , b_{mh} and b_{mff} , respectively. Action selection consists of solving the abovementioned equation using the methods described in section 2.3.

5 Experimental Results

In this section we discuss a set of experimental results that highlight several interesting aspects of multiple objective action selection for behavior-based control of a mobile robot. The experiments are carried out on a simulator, which simulates a synchro-drive Nomad200 mobile robot and its sensors. The sensors used in the experiments are a ring of 16 ultrasonic sensors for obstacle detection, and position encoders for calculation of robot position. In the example we consider the task of navigation for a mobile robot where the robot is placed at some arbitrary location and commanded to go to a goal position. This task involves three behaviors: 1) b_{ao} obstacle avoidance, 2) b_{mh} maintain target heading, and 3) b_{mff} move fast forward. For a detailed description of the implemented system and the behaviors see [7].

In the experiments five multiple objective action selection mechanisms were tested on 20 scenarios. Thus a total of 100 experimental runs were carried out using scenarios with differing complexity, obstacle density etc. In the experiments the following parameters were used in the various action selection mechanisms:

Priorities	:		b_{ao}, b_{mh}, b_{mff}
Goals	:	$(g_{ao}, g_{mh}, g_{mff})$	$= (1.0, 0.3, 0.1)$
Weight intervals	:	$(w_{ao}, w_{mh}, w_{mff})$	$= ([0.8; 1.0], [0.1; 0.2], (0.0; 0.1])$

Table 1 summarizes the results for all the experiments. Each multiple objective action selection mechanism is allocated a column in the table that lists the

results for the performance attributes listed in the first column. For all the performance attributes, but the number of successful runs, the values listed in the table are average values for the 20 runs per MOASM. In the ‘Total’ column the total average for the 100 experimental runs is listed. The values of this column thus reflect the total performance for multiple objective action selection regardless of what action selection mechanism was used. The last column lists the ideal values for the performance attributes. These values make a point of reference that substantiate the significance of the results.

	Weighted	Lexicographic	Goal prog ICW	Goal prog	Weighted Norm	Total	Ideal value
Safety (inch)	38.3	40.6	37.0	44.5	43.6	40.8	∞
$ \Theta_{rob} - \Theta_{tar} $ (deg)	36.6	44.1	36.9	47.5	38.4	40.8	0
Velocity, v (inch/s)	18.3	20.2	15.0	20.4	20.6	18.9	25
Reactivity (s)	0.14	0.14	0.16	0.14	0.17	0.15	0
# Successful runs	11	15	18	17	10	71	100
Smoothness (deg)	2.6	2.6	2.6	2.9	2.4	2.6	0
Compromise: Deviation from ideals							
Avoid obstacle	0.002	0.000	0.000	0.000	0.014	0.003	0
Maintain heading	0.154	0.077	0.060	0.068	0.293	0.131	0
Move fast	0.259	0.208	0.346	0.328	0.481	0.324	0
Combined dev.	0.415	0.285	0.406	0.396	0.788	0.458	0

Table 1

Experimental results for 20 experiments for each of the MOASMs listed in columns 2 to 6 lists. ‘Total’ is the average for all MOASM. The last column lists the ideal values as a point of reference.

Successful runs The number of successful runs is a global metric for the success of the task of navigation. It is seen that about 70% of the total number of runs is successful. The remaining 30% are caused by deadlocks or collisions. Deadlocks are situations where the robot enters a cyclic behavior like moving in a circle. When comparing the 5 multiple objective action selection mechanisms by this attribute, the results indicate that the Lexicographic, and the two Goal Programming methods are superior to the Weighting and the Weighted Norms methods.

Smoothness The total smoothness value is 2.6 degrees which indicates that the robot moves on a smooth path. The smoothness result does not vary much within the MOASMs. In order to illustrate how smooth the paths are during the runs, figure 2 depicts a set of runs. We believe two factors contribute to the smoothness of the robot’s path. The primary reason is due to the fact

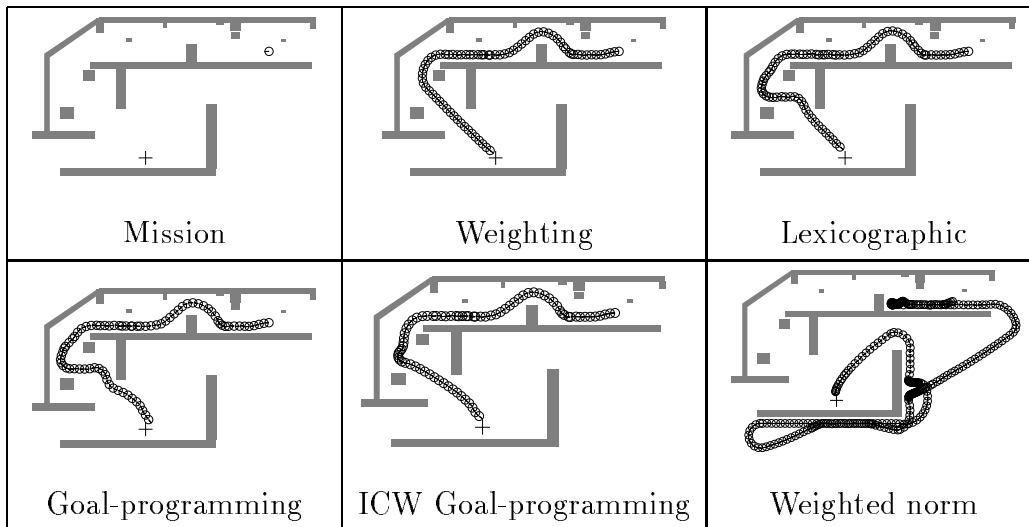

Fig. 2. In this scenario the robot smoothly follows the hallway walls, avoiding obstacles until obstacle clearance has been achieved. Then the robot moves straight towards the target.

that behaviors are blended by command fusion where all system objectives are considered simultaneously. A second reason is related to the fact that the action selection mechanisms consider the velocity and angular velocities simultaneously.

Combined deviation A powerful characteristic of command fusion mechanisms is that they select actions that benefit not only one but the collection of the behaviors that are involved in the action selection process. An attribute that is indicative of the degree of compromise is the combined deviations from ideals. An ideal \mathbf{o}^* is defined as $\mathbf{o}^* = (o_1^*, \dots, o_n^*)$, where $o_j^* = \max_{\mathbf{x} \in X} o_j(\mathbf{x})$. o_1, \dots, o_n are the objective functions. Thus for a selected action \mathbf{x}' the combined deviation for a set of objectives o_1, \dots, o_n is given by: $d = \sum_{j=1}^n |o_j(\mathbf{x}') - o_j^*|$.

Table 1 lists the combined deviation from the ideals, in the last row. The values indicate that the ‘avoid obstacle’ objective function deviates the least from the ideals, when compared to the others. Next comes the ‘maintain heading’ objective function and then the ‘move fast’ objective. This conforms to the weight values and/or priorities we have associated with the behaviors corresponding to these objectives. The results indicate that the action selection mechanisms generally do not sacrifice obstacle avoidance much for any other objective. By considering the importance or weights of each behavior in the calculation of the deviation from ideals we can determine the weighted combined deviation to 0.048. This result deviates by less than 2% ($0.048/3 \times 100$) from the ideal value.

Finally, looking at the results for each of the ASMs it is seen that the Weighted Norm ASM displays the highest deviations, which might be correlated with its low success rate.

5.1 Proof of concept experiments

As a proof-of-concept a limited number of experiments were conducted on a real Nomad200 robot to supplement the simulated experiments. In the Nomad200 simulator it is possible to run the same client program to control a real Nomad200 robot. Two of the runs are shown in figure 3. The black boxes indicate the approximate position of the laboratory walls (the gap at the left is a door). It can be seen in the figures that the robot smoothly negotiates obstacles on its way to the target point. The average speed during the experiments was about 8 inches/s.

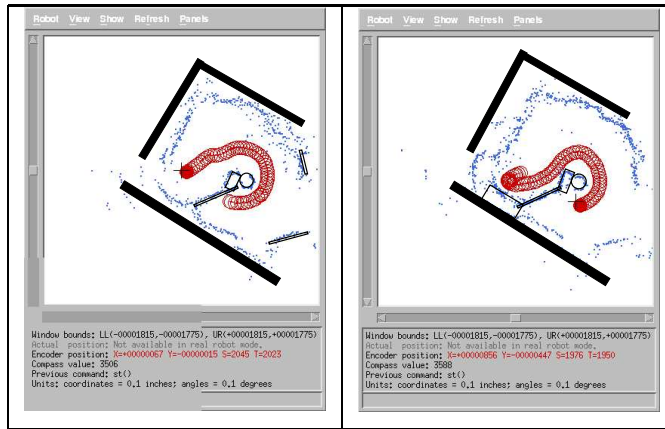

Fig. 3. Samples of experimental runs with the Nomad200 platform. The figure is created by grabbing the world view of the robot from the graphical user interface. The dots indicate obstacle positions detected by the sonars and obstacle positions are overlaid as line drawings.

6 Summary

A class of multiple objective action selection mechanisms were formulated using ideas from multiple objective decision making, which provides approaches to finding Pareto-optimal and satisficing solutions to problems with multiple objectives. This approach proposes a structured method for decomposing a complex task into a set of relevant behaviors. Each behavior then encodes a corresponding objective function. By having an explicit formulation of objective functions, this method allows for a qualitative evaluation of each alternative action against the decision objectives.

The results show that the multiple objective action selection mechanisms generally do not sacrifice important behaviors for less important ones. Still the results clearly indicate that satisficing solutions make an efficient compromise between the behaviors while taking into account the importance of each behav-

ior. By considering all system objectives simultaneously these methods enable a smooth blending of several behaviors.

For future work we intend to investigate how the proposed approach scales to more complex problems such as team robotics. Intuitively, the coordination of a group of robots seems to have similarities to the action selection problem.
