## Block-Stacking using a Multi-fingered Manipulator

Megha Gupta  
December 11, 2006

### Problem Statement:

Simulate stacking of blocks of different sizes in such a way that the resulting pile does not tumble. The blocks are assumed to be of the same shape and are moved about quasi-statically. The DaVinci Simulator has been used to simulate the stacking and it has been implemented using the Barrett arm.

### Simulation:

The DaVinci Simulator can be used to analyze the stacking process using different forces and different placements of the fingers. An existing code for block-stacking simulates free fall of blocks. However, a free fall cannot be quasi-static. So, a modified code has been written to include additional forces (applied by the robot fingers) which act opposite to the gravitational force to enable quasi-static lifting of blocks.

Since the DaVinci Simulator can currently handle two-dimensional motions only, the blocks are moved either parallel to the X-axis or parallel to the Y-axis, as shown in fig. 7. The simulation has been done using four rectangular blocks of different sizes but equal heights. Their initial positions and masses are specified using the preferences file. When starting the simulation, it is required that the user gives four arguments which specify the order in which the boxes have to be stacked. For example, if the desired order is (box3, box1, box2, box4) with box3 at the top and box 4 at the bottom, then the command to the simulator looks like:

```
./gui box3 box1 box2 box4
```

The box which is at the bottom is assumed to stay in place while all other boxes are picked up one at a time and placed in the desired position in the correct order on top of the bottom-most box. When a box is very close to its final destination, the robot arm is assumed to release it so that it falls under gravity till it makes contact with the box below. This part of the manipulation is, thus, dynamic. The simulator has in-built functionalities which ensure non-penetration at the end of each time step.

A new force controller class, BarrettForce, has been defined to simulate the force applied by the robot fingers. This force controller is attached to the boxes as and when required. However, the points of application of forces cannot be defined in the current version of DVC and all forces are assumed to be acting on the center of mass of a body. Therefore, the resultant of the forces applied by the robot fingers is applied to the center of mass for

simulation purposes. Once a box is in its final position, the force controller is detached from it.

The snapshots below show the progress of the simulation as the four blocks are stacked on top of one another. Here, the input stacking order is (box4, box1, box3, box2).

Fig. 1: Simulating stacking of blocks using the DaVinci Simulator

The simulated scenario can be extended to more than four blocks with minor modifications to the code. Parts of the code which are specific to this problem have been included in Appendix A. Now that simulation has been successful, I will proceed to implement this manipulation task using the Barrett Hand.

## Grasping:

Grasping is fundamental to manipulation. It implies immobilization of the grasped object relative to the hand [1]. The two basic constraints in grasping an object are form closure and force closure. While form closure is a purely geometrical property of a set of unilateral constraints, force closure is related to the forces being applied by a robot through contacts.

A grasp on an object  $B$  has **form closure** if and only if the object  $B$  is at an isolated point in configuration space [1]. Thus, every nearby configuration causes interpenetration.

A grasp on an object  $B$  is a **force closure** grasp if and only if we can exert an arbitrary force and moment on object  $B$  by pressing the finger tips against this object. Equivalently, any arbitrary motion of object  $B$  will be resisted by a contact force from the fingers, which means that  $B$  cannot break contact with the finger tips without some non-zero external work. That is, the total freedom of  $B$  is zero [2].

Nguyen [2] discusses how planar force closure grasps can be constructed. A force  $\mathbf{f}$  is a line vector i.e. a vector with a definite line of action. It can be represented by the following wrench:

$$\mathbf{w} = [\mathbf{f} \quad \mathbf{rxf}]^T$$

Let  $\mathbf{W}$  be a non-empty set of wrenches. The convexe  $\mathbf{W}^<$  is defined as the set of all non-negative combinations of wrenches in  $\mathbf{W}$ . A convexe is null when it contains only the null vector. It is total when it is the entire space. A planar wrench can be represented by:

$$\mathbf{w} = [\mathbf{f}_x \quad \mathbf{f}_y \quad \mathbf{n}_z]^T$$

where  $\mathbf{f}_x$  and  $\mathbf{f}_y$  are forces in the  $xy$ -plane and  $\mathbf{n}_z$  is the moment about the  $z$ -axis.

In case of a point contact with friction, the range of pure forces that can be applied through the point of contact is given by the friction cone at the point of contact. The wrench convexe has two wrenches acting along the two extreme rays of the friction cone (Fig. 2). Any force with its line of action inside this friction cone can be written as linear combination of the two extreme wrenches.

Fig. 2. Wrench cone for a point contact with friction

In case of an edge contact with friction, any force distribution along a segment of contact is equivalent to a linear combination of two forces at the two ends of the edge contact. Therefore, the wrench convexe of the edge contact is equivalent to two wrench convexes with each representing a point contact at one end of the edge contact (Fig. 3).

Fig. 3. Wrench cones for an edge contact with friction

Wrench convexe describes the set of forces and moments which constrain the object. A total wrench convexe means we can arbitrarily apply any force and moment on the object, and so we can grasp it, instantaneously rotate or translate it in any way we want. A grasp can resist arbitrary planar translation of an object if the contact forces of the grasp have directions that span the space of all directions in the plane. Torque closure can be achieved by creating enough friction on some axis of rotation of the object so that the torque produced by friction resists any clockwise or anti-clockwise rotation of the object.

It has been proved that force closure would need atleast four frictionless point contacts. However, force closure can also be achieved with two point contacts with friction at P and Q if and only if the segment PQ points out of and into the two friction cones respectively at P and Q (Fig. 4).

Fig. 4. Force closure using two point contacts with friction

Similarly, using edge contacts with friction, force closure can be achieved by even two fingers. Therefore, the Barrett Hand, which has three fingers, is sufficient to construct a planar force closure grasp for this manipulation.

### Using the Barrett Arm:

The Barrett Hand is a multi-fingered Grasper that can secure objects of different sizes, shapes and orientations. It uses industry-standard serial communication, on-board microprocessors and Grasper Control Language (GCL) to adapt to a wide variety of target objects.

It has three articulated fingers and a palm which act together to trap the target object firmly and securely within a grasp (Fig. 5). Each of the three fingers is independently controlled by a servomotor and the spread action of the fingers is independent too. When a fingertip makes first contact with an object, it simply reaches its required torque, locks both joints, switches off motor currents, and awaits further instructions from the microprocessors inside the hand or a command arriving across the communications link. The position, velocity and torque of each finger can all be processor controlled over the full range of 17,500 encoder positions [3].

The Barrett Hand has firmware that resides on the control electronics inside the palm. It needs only ASCII characters to be sent over a standard serial port. The character strings for the desired action can be built using GCL. The firmware then interprets these commands to control the motors, set and retrieve parameters or to read and write to the EEPROM.

The Barrett hand also provides a C-function Library for programming the hand using C without having to worry about management of serial communication and timing. A class Bhand is provided from which an object can be derived and used for all communications [5].

Shown in the picture below are the eight joint axes of the Barrett hand controlled by four servomotors:

Fig. 5: The eight joint axes of the Barrett Hand

The Grasper Control Language (GCL) [4] can be used either in realtime mode or supervisory mode to carry out the desired motion of the manipulator arm and fingers. In the supervisory mode, commands are given one at a time and the user then waits for processing, execution and error reporting, if any, before entering the next command. In the realtime mode, it is possible to send commands to and receive feedback from the grasper continuously, without waiting for the motors to stop moving. The firmware keeps track of the present and desired velocities and calculated the motor torque by multiplying the velocity error by the proportional gain value.

In the current implementation, both the arm and the hand have been given individual control commands, one at a time. The arm takes in commands for gravity compensation and moving from the current location to a specified destination. The hand takes in commands to initialize the motors, closing the fingers to grasp the object and opening them to release the grasped object. The complete sequence of commands used to stack three blocks is given in Appendix B.

Since there are no sensors attached to the Barrett hand, it has to be given precise locations from where the objects need to be picked up and where they need to be placed. The arm has effectively four degrees of freedom since the three freedoms associated with the wrist are absent. The hand was controlled in the supervisory mode using the Windows interface provided by Barrett and a standard serial communication link. The arm is controlled by sending commands over a high speed communication cable.

The fingers F1 and F2 can be positioned to be diametrically opposite each other by using the spread action of the hand. A force-closure grasp can then be constructed simply by

grasping the object at two opposite edges when F1 and F2 are exactly 180 degrees apart. However, in my experiment, F2 was broken and I used F1 and F3 for grasping. Since these two fingers could not be positioned exactly opposite each other, the constructed grasp did not ensure force closure but there was a very small region containing possible instantaneous centers of rotation.

Some of the improvements that can be made to the implementation are the following:

- 1) Carry out the whole stacking process using a single C code for both the arm and the hand.
- 2) Use the arm for more complicated stacking sequences like using a stack to support a second stack.
- 3) Use the DaVinci Simulator to find a stable stacking sequence that is not intuitive.

### Pick and Place Manipulation:

The first basic principle used here is that the total force acting on a body is the sum of all external forces acting on it [1]. The total force is given by:

$$F = \sum f_i \quad (1)$$

$$F = 0 \quad \text{for a quasi-static system.} \quad (2)$$

Therefore, the forces applied by the fingers should be such that their horizontal component balances out the normal reactions and the resultant upward vertical component (nearly) balances out the gravitational force (Fig. 6).

Fig. 6: Forces acting on a block as a system. F and F' are forces applied by robot fingers.

Assuming a 3-finger contact, the forces defined by F1, F2 and F3 should be such that:

$$F_{1y} + F_{2y} + F_{3y} = Mg \quad (3)$$

$$F_{1x} + F_{2x} + F_{3x} = N \quad (4)$$

where,

M = mass of the block (assumed to be known)

g = gravitational force

N = resultant normal reaction (along X-axis)

The second basic principle is that the total torque about the center of mass is the sum of the moments of all external forces about the center of mass. The total torque is given by:

$$T = \sum (x_i \times f_i) \quad (5)$$

$$T = 0 \quad \text{for a quasi-static system} \quad (6)$$

I will assume the geometric center of the block as its center of mass. The manipulation problem will, therefore, be defined as carrying out the following steps quasi-statically for each block:

- 1) Find a form closure grasp and close the fingers firmly over the block.
- 2) Raise the block vertically till its center of mass, C, reaches the desired height.
- 3) Translate the block horizontally till C reaches the desired x-coordinate.
- 4) Lower the block vertically till it makes contact with the ground or with block below it and C is at the desired y-coordinate.
- 5) Open the fingers to release the block and repeat for next block, if any.

Fig. 7: The pick and place manipulation to be executed for each block

This algorithm can be viewed as a manipulation-planning problem being reduced to a grasp-planning problem in order to find contact points first. Given the geometry of the object to be manipulated, independent regions of contact can be identified such that placing a contact somewhere within each region is sufficient to guarantee that a manipulation plan can be constructed by computing target forces to be applied at the selected contact points over time [6]. This approach is suitable for manipulation tasks where the motion is not highly dynamic and where contacts with the object can be considered as non-sliding point contacts with friction.

The forces, velocity, initial position and final position for each step will be given as an input to the manipulator by the user. The final position of all blocks should be such that their centers of mass lie in a vertical line. This will ensure that the resultant pile does not tumble down.
